SPECIAL CORRESPONDENCE.

HONG KONG.

Crusade against Anopheles.—Bubonic Plague.

DURING the early months of this year the sanitary authorities were all alert to destroy the rats of the Colony, in the hope that by that means Hong Kong might be saved from the recurrence of bubonic plague. Now the residents in the Colony are interested in a crusade against the malaria-carrying mosquito. Mr. Thomas M. Young, F.R.C.S.Edin., civil surgeon in the army, has spent the greater part of two months in searching for the breeding pools of *Anopheles* mosquito, with the result that he has found them widely distributed over the Colony—at Peak, West Point, Wanchai, etc. The researches were reported to His Excellency Sir Henry A. Blake, G.C.M.G., who took a great interest in the subject. The practical outcome is that an experiment on a large scale is being made at Magazine Gap, where is situated the military sanatorium. This sanatorium was built several years ago, but has had to be abandoned, as the inmates were attacked by such severe fever. The *Anopheles* were found in a gully close beside the building, and the intention is to clear off most of the trees and undergrowth, and to destroy the breeding pools. The work is under the direction of Mr. Young, who has had experience of the habits of mosquitos in Sierra Leone.

There are still a few sporadic cases of bubonic plague, but during the last three days there have been no fresh cases. The figures up to October 30th are: Cases reported, 1,081; deaths, 1,023.

CORRESPONDENCE.

THE EMPLOYMENT OF UNQUALIFIED PHARMACEUTICAL ASSISTANTS BY MEDICAL MEN.

SIR,—I was not surprised to see by Saturday's Glasgow newspapers that medical men practising in the West of Scotland met in large numbers to protest against the action taken by the General Medical Council in prosecuting Dr. Thomson, Airdrie, for professional misconduct connected with breaches of the Pharmacy Act.

On the first blush it would appear that the Council is doing the work of the Pharmaceutical Society by acting as the cats-paw of that body.

In a report to the Penal Committee by another Scottish member of the Council and myself—which I am sorry was confidential, and therefore could not be published—that view was argued by the reporters in the strongest manner. We felt that the prosecution of offenders under the Act should be left to the legal defenders of the pharmaceutists' position.

Personally I have never had any sympathy with the Pharmacy Act; and I have felt and expressed the opinion, over and over again, that we are gradually becoming too much like the Chinese, by insisting on examination and registration of all classes, even down to plumbers and midwives.

Again, I know that the rule of employing only qualified dispensers is broken every day by pharmaceutists themselves.

Further, I am well aware of, and have suffered personally from, counter prescribing by druggists; and I shall only be too ready to join in any general movement to put down that mischievous practice.

But, while all this is true and demanding remedy, such cannot be found in any action that could be taken by the General Medical Council. The pharmaceutists have got their Act, and it would scarcely be becoming on the part of medical practitioners to play the part of spies, as the Pharmaceutical

Council did on Dr. Thomson. The cure for counter prescribing appears to me to lie in the hands of the profession itself. Were each individual practitioner to take decided steps to prevent his prescriptions being made up in shops to which he objected, probably chemists would find it their interest to cease prescribing as they constantly now do.

Coming to the main point: Why did the General Medical Council, in view of all I have said to the contrary, resolve to prosecute Dr. Thomson? It was alleged that Dr. Thomson persisted in breaking the law of the land, and the Council felt that in so doing Dr. Thomson was accused of taking an improper advantage of his position as a registered practitioner by covering an unqualified chemist.

After hearing the evidence of Dr. Thomson and others, the General Medical Council found him guilty of the offence. But they practically gave him the opportunity of purging himself by the simple process of dismissing his unqualified and employing a qualified dispenser. No doubt such a course of action will entail considerable expense on Dr. Thomson and others like him. But the carrying out of the provisions against unqualified medical assistants led to much more serious trouble and expense to their principals, and was naturally bitterly resented by both parties.

As to the bearings of this question on direct representation, I would like to add a word or two. I hold that the profession sooner or later ought to have an equal representation to that of the qualifying bodies on the General Medical Council, and at the same time the Council be cut down to one-half its number, say to sixteen members in all. And yet in this particular case, if I am not mistaken, all the direct representatives, however unwillingly, voted for prosecution, as the offence labelled seemed to them a scandal against the profession as a body and one that had either to be proved or disproved at the earliest possible moment.—I am, etc.,

WILLIAM BRUCE, M.D.,
Direct Representative for Scotland on the General Medical Council.

Dingwall, Dec. 18th.

LONDON DIPLOMATES AND THE REFORMED UNIVERSITY.

SIR,—The letters of your correspondents Dr. J. W. Gill and "L.R.C.P., M.R.C.S., L.S.A.," in the BRITISH MEDICAL JOURNAL of November 24th, strengthen the opinion that many London diplomates feel acutely their present condition, and would hail with pleasure any concession on the part of the reformed university which would allow them to enter for its professional examinations without the present matriculation, which is clearly prohibitory. The article on that subject in the same number of the JOURNAL tends to show that even amongst young people the strain of the work involved is painfully felt; many must have doubts whether the damage to health and eyesight caused by the requirements of the present system of examination in theoretical subjects is counterbalanced by the results. That is too wide a subject to discuss here; but there can be no doubt that the matriculation in its present form is a complete bar to men engaged in general practice.

That the Birmingham University is about to grant degrees to its past students on passing a final examination is exactly to the point,[1] though considering the high standard of the London examinations such a complete concession is hardly to be expected for us.

A suggestion has reached me, from one well qualified to judge, that petitions signed by those holding the qualifications of the two Colleges should be presented to their respective Councils, backed up if possible by the teachers in the London medical schools. Unfortunately we as a body suffer from want of cohesion—not the least of the disadvantages of the present state of affairs. The work is manifestly impossible for any isolated individual, but if any of your correspondents can make any suggestion how it can be carried out, either through the medium of the BRITISH MEDICAL JOURNAL or privately, I shall be glad to co-operate.—I am, etc.

A. GREENWOOD.

Crouch End, N., Dec. 1st.

THE DIAGNOSIS OF DIPHTHERIA.

SIR,—I have read with great interest Dr. Donkin's valuable paper which appeared in the BRITISH MEDICAL JOURNAL of November 3rd.

[1] BRITISH MEDICAL JOURNAL, November 17th, 1900, p. 1479.

Therein the author concisely states the position of the clinician of the present day in dealing with acute inflammatory diseases of the throat which may be diphtheria. It amounts to this: That when in doubt, and the condition is serious, "inject diphtheria antitoxin." But cases may arise, and I have recently had occasion to see one in consultation with my colleague, Dr. A. R. Coldstream, in which there was a complete clinical picture of diphtheria, which tended from the onset to a fatal issue, and in which diphtheria antitoxin was used without avail. The bacteriological examination showed the disease to be a pure streptococcal infection.

This case is an illustration of the inadequacy of the present position of applied serum-therapeutics.

The first examination of secretion from the tonsils and subsequent examination of the membrane showed an almost pure growth of streptococci. Yet the recommendation was given to inject diphtheria antitoxin, not because it was a logical course to pursue, but in view of the patient's serious condition, in the hope that the Klebs-Loeffler bacillus had been overlooked and might show up in culture, and most of all, perhaps, because there was nothing else to suggest, as antistreptococcal serum was not available.

But a case of this kind brings prominently to view the fact that membranous, non-diphtherial tonsillitis and pharyngitis may be quickly fatal, and that we must look to the bacteriologist not only to give an immediate statement as to the predominating micro-organism present, but to keep the market supplied with antistreptococcal as well as with antidiphtherial serums to which the practitioner can resort at the shortest notice. As the infection in these cases is often mixed, and knowing that both streptococcal and Klebs Loeffler bacillary infection may lead to a fatal issue, it would often be rational practice to inject both antitoxins in the same case.

In the clinical differential diagnosis between septic tonsillitis and diphtheria, experience has led me to regard the mode of onset as most important, though possibly not pathognomonic. In streptococcal infection the patient is knocked down at once as in scarlatina, the temperature rises quickly, and often reaches the maximum on the second day while pain is the predominant symptom. In diphtheria the onset is more gradual, the disease is not ushered in by a sudden rise of temperature, and pain does not seem so distressing a symptom as the intense sense of illness. But supposing both diphtheria and streptococcal serums to be equally within our reach, and apart from the question of mixed infections, we should not feel satisfied to inject either one serum to the exclusion of the other, on such clinical considerations, in any given case. Therefore, if we do not choose to inject both, our action must be guided by the bacteriologist.—I am, etc.,

STUART TIDEY, M.D Lond., M.R.C.P. Lond.

Florence, Nov. 18th.

THE LONDON MATRICULATION EXAMINATION.

SIR,—I must thank the Secretary of the Girls' Public Day School Company for his courtesy in giving me the statistics I asked for. I am glad to acknowledge that the seven schools which have medical inspectors are not behindhand in well-regulated physical exercise, and in preventing any pupil from overstraining herself in preparing her lessons at home. The remaining schools of the total thirty-three are, however, evidently behind these progressive seven. The term "physical exercise" was intended to include far more than the mere possession of playgrounds. I know that many girls do in fact manage to evade all exercise except compulsory drill once or twice a week, and the daily walk to and from school. I also know many who habitually exceed the home time table which is so excellent theoretically; especially is this the case during the examinations at the end of term. I quite recognise that the girls and their parents are much to blame; but whereas the one business of teachers is the welfare of their pupils, parents have to earn their bread or to superintend younger children, and can in most cases hardly be called specialists in education.

I fail to see why parents at twenty six schools should object to the plan of medical supervision which has proved so invaluable at seven schools. It is to such a Company as this, which is and has so long been the leader in the higher education of girls, that other girls' schools look for an example. May I suggest (1) that physical exercise be made compulsory

xcept in the medically unfit; (2) that a medical inspector at every school should determine what girls should be exempted from compulsory exercise and what girls should follow them in a modified form; (3) that an occasional unexpected short examination should be substituted for the regular long examinations at the end of term, and more especially in the hot summer term; (4) that the head mistress occasionally ask the medical adviser to address a meeting of parents and teachers on some point connected with the health of girls?—

December 18th. YOUR CORRESPONDENT.

CLASSIFICATION OF DISEASES.

SIR,—In connection with the papers by Drs. MacIlwaine and Powell White in the BRITISH MEDICAL JOURNAL of December 15th, may I draw attention to a paper on Classification in Pathology, by Charles W. Cathcart, F.R.C.S.Eng. and Edin., published in the *Edinburgh Medical Journal* for July and August, 1896, in which he advocates "cause" as a desirable primary basis of classification, and in this direction draws up a rational classification of disease?

He applied this method in rearranging the Museum of this College, of which he was until lately the Conservator, and as this rearrangement is approaching completion, Dr. MacIlwaine may be pleased to learn that soon our Pathological Museum, at any rate, will not be in that chaotic state to which he refers all pathological museums.

I may state, in addition, that our students are, every year, taking more advantage of the chances afforded them of studying surgery and surgical pathology in the Museum.—I am, etc.,

THEODORE SHENNAN,
Conservator of the Museum of the Royal College of Surgeons of Edinburgh.

Edinburgh, Dec. 18th.

TREATMENT IN INFIRMARY LOCK WARDS.

SIR,—Will you kindly allow me on behalf of, and by direction of, the Infirmary Medical Superintendents' Society to protest against two anonymous letters on the above subject, published in the BRITISH MEDICAL JOURNAL of November 24th and December 15th respectively, and also your own comment on the first letter?

I am of opinion that you have been assured very wrongly concerning the management of these wards, and am confident that, so far as the experience of the Society extends, the nursing of such wards is carried out without any distinction from other wards, the same care being bestowed as on the other branches of the work, and that it is not neglected as you suggest.

I should like to point out that the statements made in the first letter—to which your comment related—were apparently based on the uncorroborated assertions of a discontented patient. If your correspondent is aware of such grave defects in the administration of infirmaries, would it not have been better for him to have given us chapter and verse from his own experience rather than rely on the statements of a patient? Poor-law patients are not the most unbiassed or the most truthful of people.

I should like further to inquire whether "M.D.Lond., D.P.H.Cantab." brought "the incidents" which he states "are apt to occur" under the notice of the authority or authorities of the infirmary or workhouse at which he had such unfortunate experiences.

If the authority be a medical one, would it not have been more in accordance with professional etiquette to do so; and in the event of his failing to get what was right done, to have published the facts with full names and details? We do not wish to criticise some of the statements he makes on the authority of a patient, but possibly a little cross-examination would elicit some material facts which might put a very different complexion on affairs; and even as it stands, his account seems to merit criticism in many parts.—I am, etc.,

WM. J. KEATS, D.P.H.Lond., etc.,
Honorary Secretary.

Camberwell, S.E., December 19th.

*** Our correspondent must see that the gravamen of the statements made by "M.D.Lond., D.P.H.Cantab." does not rest on the "uncorroborated assertions of a discontented patient."

THE RESTING POSITION OF *ANOPHELES*.

SIR,—Drs. Sambon and Low[1] have called into question the accuracy of the statement "that the relative positions assumed by *Culex* and *Anopheles* are.....strikingly different," and appear to consider it erroneous. That there is a difference is apparent to any one who has observed the habits of both genera, but the positions assumed by them when at rest are more nearly alike than one would suppose on seeing them for the first time.

The *Anopheles* of St. Lucia (? *A. Albitarsus*) does not, like that described by Mr. Austen in his report, stand on its head (would it not be more accurate to say "on the end of its nose"?), but rests at a slight incline from the support, certainly not more than 45 degrees. When resting on the two front pairs of legs—its usual position—the last pair is seldom at rest, for the two legs are constantly describing circles in the air, not at all unlike the arms of a man swinging Indian clubs.

The different angles assumed by the different species of *Anopheles* when at rest would depend upon the relative lengths of the two first pairs of legs. A slight increase in the length of the middle pair would have the effect of tilting the posterior part of the body away from the support, thus increasing the angle. I say when at rest because a mosquito can alter its position, irrespective of the length of its legs, when for any reason it has occasion to move to another place without flying, or when feeding. As far as my own observations are concerned, the last pair of legs in both *Anopheles* and *Culex* are seldom, if ever, used as a support when resting, but are only used as organs of locomotion when walking or as balancers when flying.

There is one point of difference, however, which appears to have been passed over both by Major Ross and Mr. Austen, and by Drs. Sambon and Low, which enables one to distinguish at a glance between the two genera, regardless of the position assumed by the insect when resting. In *Anopheles* the proboscis and body are in the same straight line in whatever position the insect may be, while the proboscis of *Culex* always forms an angle with the body. Even when *Culex* raises her proboscis (as when in search of food through a net), so as to be as nearly as possible in a line with the body, the junction of the proboscis with the body is something like the attachment of a bayonet to a rifle—nearly parallel, but not in a line with the body—while the proboscis and abdomen of *Anopheles* taper away from the thorax like the two ends of a spindle.

Dr. L. O. Howard, the Entomologist of the United States Department of Agriculture, has carefully observed the resting positions of the adult *Anopheles*.[2]

He finds that when resting upon a horizontal surface, such as the ceiling of a room or the covering of the breeding jars, the insect clings with its four anterior legs in a nearly perpendicular position, its beak thrust forward toward the surface to which it clings. The hind legs are frequently in motion, but as a rule hang downward, with more or less of a bend at the knee-joint (femoro-tibial articulation). When resting upon a perpendicular surface, however, such as the side wall of a room or the side of a breeding jar, the body is held only at a comparatively slight angle from the surface. Sometimes it is nearly parallel to the surface. At other times it assumes an angle of 10° to 20° (occasionally even as great an angle as 30° to 40°), the proboscis being held nearly in a line with the body. Here again the insect supports itself by the four anterior legs, the hind legs dangling down with more or less of a bend at the knee. This position is common to both males and females.....When the body is held parallel, it will generally be found that one of the middle or hind legs has been broken off. They are very delicate, and readily break.

Dr. Howard reproduces some drawings of Mr. C. O. Waterhouse, of the British Museum, which illustrate the relative positions assumed by *Anopheles* and *Culex* better than any others that I have seen. Mr. Waterhouse sums up the points of difference in two short sentences. He writes[2]: "Whatever may be the attitude of *Anopheles*, it is all in one line; *Culex* is angular, humpbacked."

If the proboscis and body of *Culex* formed a straight line, as they do in *Anopheles*, the different attitudes assumed by them when at rest would not be so striking as to form one of the means of distinguishing between them.

I know of no species of *Anopheles* whose body and proboscis

[1] BRITISH MEDICAL JOURNAL, October 20th, 1900, p. 1158.

[2] *Bulletin*, No. 25, New Series, United States Department of Agriculture, Division of Entomology, p. 33.
Loc. cit., p. 34.

do not form a straight line, nor have I yet seen a *Culex* in which they do not form an angle.—I am, etc.,

St. Geo. Gray, M.B., B.Ch.(Univ. Dubl.),
Colonial Assistant Surgeon, St. Lucia, West Indies.

November 16th.

Sir,—I have read in the British Medical Journal of October 20th (the last which has reached me) the article by Drs. Sambon and Low on the above subject.

All credit is due to Major Ross, I.M.S., and Mr. Austen (a well known expert), for being the first to draw attention to the distinctive attitude assumed by *Anopheles* when at rest—distinctive at least so far as the species inhabitating Sierra Leone are concerned. I can testify from personal observation on the West Coast of Africa that their observations were absolutely correct. It remained for other observers to discover exceptions, if any, in other parts of the world.

Until now, I believe, no one has recorded an exception except Professor Grassi. So far as India is concerned, the rule laid down by Dr. Ross and Mr. Austen holds good for three out of the four species of *Anopheles* I have observed. The exception is a species whose acquaintance I have just made at Dhond, which certainly does stand with the posterior part of its body a little nearer the support on which it is resting than the other three species do, but its characteristic bradawl shape, with its proboscis and palpi held almost in a line with its body, distinguishes it at a glance from any of the many species of *Culex* with which I am acquainted in India and elsewhere.

We are compelled, therefore, to admit that the resting position hitherto believed to be characteristic of all members of the genus *Anopheles* certainly is not characteristic of one or two species. I feel sure, however, that all who have made a study of the subject will agree with me that the resting position *plus* the shape of the insect do afford in practice a distinctive generic difference between *Anopheles* and *Culex*. The former carries its body at at angle of about 45 degrees with the surface upon which it is resting; the latter *Culex* carries its body either parallel to the surface on which it is resting or with the posterior end pointing more or less towards it, and its head and proboscis at a considerable angle with the body, much as an elephant's head and trunk are carried. The drawings representing insects in these attitudes appearing (see Plates II and IV) in my book on *Mosquitos and Malaria* (Sampson Low and Co., Limited) were made by me from life whilst the insects were resting upon strips of paper in test tubes. I was careful to ascertain that they maintained the same attitudes when at liberty and resting on a wall.

I hold, therefore, that Drs. Sambon and Low are wrong in stating that "the resting attitude of mosquitos loses all the importance attributed to it as a diagnostic character between the *Culex* and *Anopheles* genera." Obviously the distinction does not hold good in all cases; but I believe, nevertheless, that it does so in most, and that it will, therefore, still be found of value.

Whilst making the drawings above mentioned, I observed another point of difference between the members of the two genera I had under observation, as pointed out in my book (in the explanations to Plates II and IV). In the case of *Culex*, the last pair of legs were often held with the tarsi curved up above the body; whereas, in the case of *Anopheles*, the last pair of legs, though often held in a similar manner, were kept below the body. This may or may not be found to apply to all members of these genera. It remains for other observers to say. At all events, I never observed the tarsi of any species "pointing downwards," as described by Drs. Sambon and Low.—I am, etc.,

Bombay, Nov. 9th. Cuthbert Christy.

ERYTHEMATOUS RASH DUE TO BORIC ACID.

Sir,—I have read with interest the case reported in the British Medical Journal of November 24th, by Dr. Handford of Nottingham, on an erythematous rash due to boric acid used for washing out a dilated stomach. In a clinical lecture on drug eruptions, published in the *Clinical Journal*, September, 1897, I recorded a case of boric acid poisoning with intense erythematous eruption from the application of boric acid ointment over extensive burns. This case unfortunately ended fatally. Since then I have observed from time to time quite a large number of erythematous eruptions due to absorption of this material from dressings applied to wounds, etc. In one case, which I reported in the *Lancet*, January 28th, 1899, the boric acid was used for washing out the bladder. I feel convinced that many cases of eruptions produced by boric acid occur and are never diagnosed as such, and that in this respect boric acid is not so harmless an antiseptic as is generally supposed.

My object, however, in writing this letter is to point out how very simple is the process for detecting its presence in the urine and how easy it is to ascertain by this means in doubtful cases of toxic eruption, whether there is boric acid in the system or not. As we know, it is more or less freely used as a food preservative, and its detection in the urine in doubtful cases, may lead to a successful diagnosis and immediate relief from the often troublesome eruption. In this connection it is worth noting that for some days after the boric acid has been stopped it is to be found in the urine. The method I adopt is that described in Morrow's work on *Drug Eruptions* (New Sydenham Society, 1893, vol. 148, page 403):

Make the urine alkaline by soda, evaporate to a syrup, mix with some pure white sand, evaporate to dryness. Powder the residue, cover it with alcohol and add a few drops of strong sulphuric acid. On igniting the alcohol it will burn with a green or green bordered flame.

The whole process is very simple and does not occupy more than a few minutes.—I am, etc.,

Sheffield, Nov. 25th. Arthur Hall.

THE SCALE OF FAHRENHEIT'S THERMOMETER.

Sir,—In the British Medical Journal of October 20th just arrived, I read with much interest the article under the above heading. I certainly have been under the impression, when and how obtained I cannot say (from a book perhaps, from a lecture possibly), that the scale of Fahrenheit's thermometer owned relationship with the temperature of the blood; but the explanation as to the principle of its construction, which I have always accepted as a matter of course though on what authority I do not know, differs from that mentioned by Sir Samuel Wilks. It is that the thermometer is in reality of centigrade construction; that originally the blood temperature was taken as one fixed point, the lowest temperature which was then believed to be possible was made the other fixed point, and the intervening degrees of temperature were represented by dividing the scale between these fixed points into 100 divisions. The lower of the two fixed points was, I understood, the temperature of a mixture of ice and salt.

It was then found that water froze at a temperature corresponding to the 32nd division on the scale, and that its boiling point was at the 212th division on the scale continued upwards. It may be asked how it is, if this explanation is to be believed, that the accepted temperature of the blood is placed on the Fahrenheit scale of to-day at 98.4° and not at 100°. The explanation I would suggest is that although the original fixed points were probably, as stated, the temperature of the blood and of the ice and salt mixture, it is not improbable that the blood was before long discarded as a standard furnisher—its temperature being found somewhat variable—in favour of freezing water, the temperature of which was seen to be invariable. Then having these fixed points (the temperature of the ice and salt mixture and of freezing water) the scale between which was marked into 32 divisions, it is, I think, apparent that as the art of making thermometer tubes of uniform calibre improved, it was found that the point at which the mercury or other expanded fluid stood when at the temperature of the blood corresponded to a point on the scale between the 98th and 99th divisions, for the point on an instrument so constructed would be no longer predetermined, having been discarded as a fixed point in favour of that of freezing water.

In other words, it appears that although on the thermometers first made—the calibre of which was doubtless less accurate than in subsequently constructed instruments—the expansile fluid at the temperature of freezing water was found to correspond to 32° (the scale between the fixed points mentioned being divided into 100 parts), nevertheless it would now, I take it, be found in the case of an accurate tube so divided that the freezing point of water did not correspond to the 32nd division on the scale, but that it lay midway be-

tween the 32nd and 33rd. Just as it is conversely found that when the standard of graduation is made by dividing the interval between points marking respectively the temperature of the salt and ice mixture and of freezing water into 32, the mercury at blood heat stands at 98.4°, and not at 100°.—I am, etc.

St. George's Hospital, Bombay, Nov. 8th.

THE BIRMINGHAM CONSULTATIVE INSTITUTION.

SIR,—At a meeting of the Representative Committee of Consultants and Specialists, held on December 3rd, the enclosed resolution was adopted.—I am, etc.,

THOMAS WILSON.

Birmingham, Dec. 19th.

Resolved: That this meeting of the Representative Committee of Consultants and Specialists of the City of Birmingham desires to congratulate the Medical Defence Union and its able and energetic Secretary, Dr. A. G. Bateman, upon the successful result of the prosecution of Dr. Ward Irvine before the General Medical Council, and returns very sincere thanks for the assistance afforded to the medical profession in Birmingham.

THE TREATMENT OF DYSENTERY.

SIR,—In the article on the above by Dr. Watkins-Pitchford it would appear that many of the older methods of treating dysentery are being superseded by newer methods without any very adequate reason. Can it be that the older methods have not had a fair trial? Saline aperients, he writes, have been found "all but useless" because they could not be given in the initial stages. Undoubtedly they are most useful in the initial stages, but I venture to think they would also be very useful if judiciously employed in the later stages. Magnesium sulphate is the only saline aperient I have used, and this I have found of use in all stages when given in ʒj doses every hour for three or four, or even eight doses. Originally it was recommended in ʒij doses every two hours, and is used by some in this manner now. This "evacuant method" empties the loaded vessels of the intestine, causing a watery yellow evacuation to take the place of the mucus and blood, which is passed with so much straining; and lessens the number of the evacuations as well as the "griping," which is so distressing in the acute stage. When this result is obtained the saline should be followed by Dover's powder and bismuth, but repeated if the stools again become dysenteric.

The ipecacuanha cure is of necessity "much credited," having proved so very successful in the past, but has nothing whatever to do with Dover's powder! I remember well Surgeon General Maclean in his lectures citing a case in which the ipecacuanha treatment proved most beneficial after large doses of Dover's powder had been given even *ad nauseam*.

Then as regards diet, surely "the fact that milk was not a suitable diet" will be questioned by many who have had the treatment of this fell disease in the tropics. Of course there are some very exceptional cases where milk in any state of dilution seems objectionable (for example, in the case of milkmen), as also cases in which the magnesium sulphate or ipecacuanha are useless, but I think it will be found that in the majority of cases one or other of these forms of treatment with a careful dietary, consisting almost exclusively of milk or some "thick panada" will be as beneficial, if not more so, than many of the various forms of treatment which are now being tried.

In the chronic form of this disease I would again strongly recommend a trial of Indian hemp. Ten minims of the tincture rubbed up with pulv. acaciæ gr. x and bismuth. subnitr. gr. x in aq. menth. pip ʒj ter die will be found most useful. In addition wet packs or poultices to the abdomen, rest in bed, avoidance of alcohol, tobacco, and chills, with a carefully-regulated but nourishing diet, will, I think, assist most materially in overcoming that prolonged anæmic stage of the disease which so often wearies out both the patient and his medical attendant.—I am, etc.,

G. F. POYNDER.

Bedford, Nov. 13th.

SPRAINS OF THE INTERNAL LATERAL LIGAMENT OF THE KNEE.

SIR,—I have been much interested in the communication from Mr. Joseph Griffiths, of Cambridge, in the BRITISH MEDICAL JOURNAL of October 20th, on the above subject, especially as I was a sufferer from that trouble in my young days, having sprained the internal lateral ligament of my knee 41 years ago, when I was a pupil to the late Sir G. M.—then Mr—Humphry, at Cambridge. For two or three years I had a great deal of trouble, and when a student at St. George's I consulted Mr. Heather Bigg about having an apparatus to support the knee. I suggested a somewhat similar apparatus to the one used by Mr. Griffiths. Mr. Bigg, however, thought that it would be difficult to keep it in position, and made me instead a steel apparatus attached to the boot, to the leg, and the thigh, accommodating itself to every movement, and holding a band round the knee in such a way that it would seem impossible to sprain the internal lateral ligament with this strong support.

I wore this for a year or more with some slight benefit, but it was not a practical success, for two or three times I sprained the ligament while wearing the apparatus, and it then became clear to me that no mere mechanical support could be worn strong enough and stiff enough to effectually support the internal lateral ligament of the knee in an active young man. I then got a laced knee-cap with a leather splint at the back, and this was a complete success, not from its superior mechanical support, but because it limited the movements of the joint just sufficiently to make me always careful with that knee. I never had a renewal of the sprain while wearing this. Once or twice after I left it off I had slight reminders of the trouble, but the fact of having worn that knee-cap for a few years has engendered a lifelong habit of being a little more careful with that knee; while it has not prevented me from doing a fair amount of mountain climbing. The feeling I speak of became automatic. Mr. Griffiths's is the first communication I have seen on this subject, but the trouble is a common one. I have, however, always found that this peculiar kind of knee-cap, if properly worn, soon cured the annoyance in all who consulted me on the subject.—I am, etc.,

WALTER G. WALFORD.

Finchley Road, N.W., Nov. 16th.

ABDOMINAL OPERATIONS: THE CASE OF DR. IMLACH.

SIR,—Mr. Arthur Wiglesworth unfortunately does not even understand the contention of those who have been writing on this subject.

The suggestion is not that Dr. Imlach was a pioneer of oöphorectomy, but that he was a pioneer in the surgical treatment of several abdominal diseases which up to that date had been more or less neglected. Notably was he a pioneer in the treatment of abdominal and pelvic hæmatocele by abdominal section, and in the (conservative) surgical treatment of prolapsed and tender ovaries (oöphorrhaphy).

Fortunately this does not admit of any controversy. The Committee who sat upon his work, after considering his cases of hæmatocele treated by operation, wrote as follows: "On one point they (the Committee) feel decided, namely, that in ordinary cases of pelvic hæmatocele, it (the operation) is not to be recommended."

We now know that ordinary cases of pelvic hæmatocele are due to tubal pregnancy; it is only the extraordinary ones to which some other cause can be assigned.

Whatever, therefore, may have been the value of contemporary criticism on Dr. Imlach's methods in other respects, it is evident that this judgment was very much mistaken. Should not the signatories anticipate the verdict of the future—may I not say the verdict of to-day—by gracefully acceding to Dr. Imlach's request?—I am, etc.,

JOHN W. TAYLOR.

Birmingham, Dec. 15th.

KIRKES' HANDBOOK OF PHYSIOLOGY IN AMERICA.

SIR,—Not having seen the letter of Mr. John Murray upon the subject, Professor Halliburton's communication in the BRITISH MEDICAL JOURNAL of December 15th was the first intimation to me that my name continues to appear upon the title page of what may be called an unauthorised edition of *Kirkes' Handbook of Physiology*, published in America, as joint editor with (the late) Mr. Morrant Baker. The well-informed reviewer of the *Boston Medical and Surgical Journal*, quoted

by Professor Halliburton, gives a pretty accurate account of the history of the book in question. The first edition of *Kirkes' Physiology* was brought out in 1848 by Dr. Kirkes, assisted by Mr. (afterwards Sir) James Paget, and these names appeared upon the title page (I think) until 1869, when Mr Morrant Baker brought out the sixth edition. Mr. Baker continued to be sole editor until 1880, when I assisted him in bringing out the tenth edition. The book continued under our joint editorship until 1892, when the thirteenth edition was published; this was revised in 1894, and was, according to the preface, to be looked upon "in certain respects as a new edition." As far as I can recollect this revision was done by me. After the issue of this revised edition, Mr. Morrant Baker and I ceased to be editors; the former in consequence of failing health, and I because I had given up the teaching of physiology. The next edition was edited by Professor Halliburton, and was to a large extent a new book, with a complete rearrangement of the subjects and a much enlarged scope. The editor and the publisher were certainly justified in looking upon the fourteenth edition therefore as practically a new work upon physiology. Perhaps it would have been better if the old title had been given up, but there were no doubt cogent reasons against this. Since 1894, then, neither Mr. Morrant Baker (whose lamented death occurred in 1896) nor I have had anything whatever to do with the editing of *Kirkes' Handbook*, and the continued use of our names in this connection is a most unwarranted and unjustifiable proceeding.—I am, etc.,

Queen Anne Street, W., Dec. 18th. VINCENT D. HARRIS.

THE TOXIC ACTION OF CACODYLATE OF SODIUM.

SIR,—Professor Armand Gautier's treatment of phthisis has been so enthusiastically advocated in the columns of the daily press, and we have been so repeatedly assured that cacodylate of sodium, although it contains 55 per cent. of arsenious acid, is absolutely innocuous even in large doses, that many practitioners will feel inclined to give it a trial. I hope, however, if they do so they will exercise a more than ordinary amount of caution, and that instead of beginning with a dose of 3 or 4 grains they will be content to prescribe a very small fraction of that quantity. I have now under my care a young woman suffering from moderately advanced phthisis. I ordered her 1 gr. of the drug in a pill three times a day. The specimen was carefully selected, and was obtained from a well known maker in Paris. After taking eleven pills she suddenly developed symptoms of arsenical poisoning. She suffered from constant nausea and vomiting, there was complete anorexia, the tongue was raw and irritated, the conjunctivæ were inflamed, the eyelids were œdematous, and there was considerable prostration. The breath had a gangrenous odour, there was tenderness on deep pressure along the course of the nerves, especially in the lower extremities, and she was unable to move the left leg or extend the left wrist. On suspending the treatment the acute symptoms subsided in twenty-four hours, but the loss of power in the leg and in the arm persisted for three days. There was no diarrhœa, and there was no albumen in the urine. The physical signs in the chest underwent no alteration. She had been under observation for some weeks before the treatment was commenced, and the neuritis was not due to any extraneous cause. It may be argued that she was peculiarly susceptible to the action of arsenic. On that point I have no evidence to offer, but if ever again I prescribe so lethal an agent as cacodylate of sodium, it will not be in the heroic doses recommended by French physicians.—I am, etc.,

Welbeck Street, W., Dec. 18th. WILLIAM MURRELL.

OBITUARY.

COURTENAY CHARLES PARSONS, M.R.C.S., L.R.C.P.,

Civil Surgeon[8] South African Field Force.

EVERY member of the British Medical Association will have read with profound regret of the death of Civil Surgeon Courtenay Parsons, the eldest son of Dr. Charles Parsons of Dover, recently Treasurer of the Association.

Mr Courtenay Parsons began his medical work as a pupil at the Carlisle and Cumberland Infirmary, having previously matriculated at Cambridge for the Science Course. Subsequently he completed his medical curriculum at St. Mary's Hospital, London, and obtained the diplomas of M.R.C.S. and L.R.C.P. in 1896. Shortly afterwards he was elected Assistant House-Surgeon to the North Staffordshire Infirmary, where he remained fifteen months. On relinquishing this office he worked with several practitioners in order to become familiar with the routine of private practice.

When the war in South Africa broke out he volunteered for service, and in the early spring of this year he was appointed by the War Office Civil Surgeon to the 21st Field Hospital, with which he served continuously for eight months, with two colleagues. The exigencies of the campaign left him at length in sole charge whilst trekking for weeks continuously. It was, however, only early in November that he complained of feeling a little bit fagged, and he was looking forward to a little rest which he hoped to get on arriving at Harrismith, but otherwise was feeling very fit. On November 30th an official telegram announced that he was "dangerously ill," and on December 3rd another conveyed the intelligence that he had died of enteric fever on December 2nd. He gave his very best service even to the utmost for his fellows, and the rest which he needed after such continuous arduous work came too late to save him.

His brother, Lieutenant Francis Newton Parsons, of the Essex Regiment, who was awarded the V.C. for conspicuous gallantry at the battle of Paardeberg and on other occasions, was killed in action at Driefontein on March 10th. The deepest sympathy will be felt with Dr. Parsons in the loss of two such sons.

ALEXANDER DEAS DAVIDSON, M.A., M.D.CANTAB., M.R.C.S., L.S.A.,

Ophthalmic Surgeon, Swansea General and Eye Hospital.

WE record with much regret the death of Dr. A. D. Davidson, of Swansea, which occurred on December 7th. He had been in indifferent health since a severe attack of influenza three years before, and the immediate cause of his death was acute phthisis. The son of a naval surgeon, he was born in 1849. He entered at Clare College, Cambridge, and took the B.A. degree with honours in 1872, and the M.A. in 1875. On leaving Cambridge he commenced the study of medicine at St. Thomas's Hospital. He became M.R.C.S. and L.S.A. in 1877, and M.D. in 1880. After holding the posts of Ophthalmic Assistant at St. Thomas's Hospital and Resident Clinical Assistant at the Bethlem Hospital, he, in 1882, commenced practice in Swansea. Shortly after he became Medical Officer in the out patient department of the Swansea General and Eye Hospital, and a little later Ophthalmic Surgeon to the hospital, a post which he held until four months before his death. He was a Medical Officer of the Swansea Provident Dispensary, and a member of the South Wales and Monmouthshire Branch of the British Medical Association. He was one of the best known men in his profession in Swansea, and had a considerable reputation as an ophthalmic surgeon throughout South Wales. His loss will be greatly felt.

ETIENNE JULES BERGERON, M.D.,

Perpetual Secretary of the Paris Academy of Medicine

DR. BERGERON, Perpetual Secretary of the Académie de Médecine, who died recently, was born in 1817. He studied medicine in Paris, where he took his degree in 1845. He gave special attention to diseases of children, and was for many years physician to the Hôpital Sainte Eugénie, now the Hôpital Trousseau. Besides being a learned and skilful physician, M. Bergeron was also a distinguished hygienist. He was a member of the Council of the Public Hygiene of the Seine Department, where he made himself prominent by a number of valuable reports, among which may be mentioned one on the making of wine (1870), and another on the repression of alcoholism (1872). He succeeded Poëlard as Perpetual Secretary of the Academy in 1887. Dr. Bergeron was a man of the highest integrity of character and had a lofty sense of the dignity of his profession. His writings consist chiefly of reports presented to the Committee of Hygiene and of funeral discourses on deceased members of the Academy delivered every year in his official capacity: in this difficult species of literary composition he was a past master. Among

his other writings may be mentioned Monographs on Quinine Eruptions (1876); on the Geographical Distribution of Ringworm in France, and on Typhoid Jaundice. He took an active part in the creation and development of the Œuvre des des Hôpitaux Marins, of which he was president.

DR. JAMES MICHELL WINN died at his residence in Hampstead on December 8th in his 92nd year. He was, it is stated, the oldest M.D. of Glasgow, and also the fourth in the list of the Members of the Royal College of Physicians; he was not the oldest in point of age, there being a senior to him by six months among the Fellows of the College. Dr. Winn was born in the parish of Budock, in Cornwall, on December 25th, 1808. When about five years of age he went to reside with his parents at Lisbon, and was a resident in the Peninsula when the battle of Vittoria was fought in 1813. On returning to England his family resided for several years in London. Dr. Winn was educated at the Stockwell Park Academy. He commenced his medical studies at St. George's Hospital under Sir Benjamin Brodie and Dr. Chambers. He heard Mr. Abernethy deliver a lecture on one occasion, and was struck with the clear and practical style of the lecturer. On leaving St. George's Hospital he went in 1832 to the University of Glasgow to study for the M.D. degree. At that time the cholera had made its first appearance in England, and the average daily deaths at Glasgow amounted to upwards of one hundred. This gave him a good opportunity of studying the nature and treatment of that complaint at the Cholera Hospital. On returning to England he was appointed Honorary Physician to the Royal Cornwall Infirmary, a position he retained for fourteen years. In 1852 he settled in London, where he made psychology his chief study, and contributed numerous articles on that subject to the *Journal of Psychological Medicine*. He had written previous to this in 1848 a treatise on *General Paralysis of the Insane*. In a work on the *Nature and Treatment of Hereditary Disease*, published in 1869, he propounded a theory that all hereditary disease was interchangeable—in other words, mutually convertible. Dr. Winn was buried at Kensal Green on December 12th.

DR. D. E. SIEGENBECH VAN HEUKELOM, Professor of Pathology and Forensic Medicine in the University of Leyden, who died recently at the age of 50, was originally engaged in business. At the age of 29 he was able to gratify his inclination for medicine, and he began his studies in 1880. He graduated at Leyden in 1885, and was soon appointed Assistant in the Boerhaave Laboratory, where he devoted himself with great enthusiasm to pathological research. The fruits of his labours were published in the *Nederl. Tijdschrift voor Geneeskunde*, *Virchow's Archiv* and *Zeigler's Beiträge*. A collection of his papers was embodied in the *Recueil de Travaux du Laboratoire Boerhaave*, which was published by Brill of Leyden in 1899. In 1888 he was appointed to the newly founded Chair of Pathological Anatomy. As a teacher he made a great impression on his pupils, not only by his knowledge and enthusiasm, but by his fine personal character. Professor van Heukelom, who was a member of the Leyden Town Council, took the deepest interest in social questions, and was untiring in his efforts to improve the administration of lunatic asylums and prisons, and generally to better the condition of the people.

DEATHS IN THE PROFESSION ABROAD.—Among the members of the medical profession in foreign countries who have recently died are Dr. Rufus P. Lincoln, one of the foremost laryngologists of New York, who was one of the first to use the electric cautery in operations on the throat, aged 59; Dr. Moses Clarke White, Professor of Pathology in Yale Medical School, aged 81; Dr. Richard Altmann, Extraordinary Professor of Anatomy in the University of Leipzig, aged 48; and Dr. Durand, of Gros, one of the first medical men in France who gave attention to hypnotic suggestion. He was the author of a *Traité de l'Electro-Dynamique Vital* and a *Cours de Braidisme*, both of which were published in 1850. Dr. Gros, who was born in 1826, had to go into exile at the time of the *Coup d'Etat*, and did not return to his native land till 1860. He meddled little with politics afterwards, but was an unsuccessful candidate for the Senate in 1892.

ROYAL NAVY AND ARMY MEDICAL SERVICES.

THE ALEXANDER MEMORIAL PRIZE.

OWING probably to the pressure of work entailed on the officers of the Royal Army Medical Corps by the war in South Africa, no essays, competing for the prize of £50 and a gold medal, have been received within the limits of time required.

The Committee have therefore resolved to offer the same subject for the next competition, namely, "Injuries to joints and long bones, caused by modern small-arm projectiles: their nature, diagnosis, and treatment, with special reference to the appliances required and available on field service."

Essays must reach the President of the Committee on or before December 31st, 1902, must bear a brief motto, and be accompanied by a sealed envelope similarly superscribed, containing the name and address of the author. No essay should exceed about 20,000 words, exclusive of tables, which may be added in the form of appendices. The competition is limited to executive officers of the Royal Army Medical Corps on full pay, and professors and assistant professors at Netley are not eligible while so employed.

THE ROYAL NAVY MEDICAL SERVICE.

THE following appointments have been made at the Admiralty:—CHARWORTH L. NOLAN, M.B., Staff-Surgeon, and HENRY W. W. TOWNSEND, M.A., Surgeon, to the *Blenheim*, January 1st; EDWARD T. MEAGHER, Surgeon, to the *Briton*, January 1st; J. R. MUIR, M.B., Surgeon, to the *Jupiter*, January 1st; CHRISTOPHER L. W. BUNTON, M.B., Surgeon, to the *Forte*, December 13th; SYDNEY CRONEEN, Surgeon, to the *Raven*, December 13th; JOHNSTON H. ACHESON, M.B., Staff-Surgeon, to the *Anson*, undated; H. C. ADAMS, W. E. GRIBBELL, and H. V. WELLS, Surgeons, to the *Vivid*, for disposal, January 19th; L. LINDOP, J. WHELAN, and J. VERDON, Surgeons, to the *Duke of Wellington*, for disposal, January 19th; J. M. H. CONWAY, A. J. SHELDON, and C. R. RICKARD, Surgeons, to the *Wildfire*, January 19th.

The appointments of Staff-Surgeon J. H. ACHESON, M.B., and Surgeon R. B. AINSWORTH to the *Anson* have been cancelled.

ROYAL ARMY MEDICAL CORPS.

THE undermentioned Surgeons on probation are appointed Lieutenants, dated November 29th:—HENRY J. MCGREGOR, M.B.; WILLIAM R. P. GOODWIN, JOHN H. BRUNSKILL, M.B.; ARTHUR C. DUFFEY, M.D.; ARTHUR W. GIBSON, CHARLES D. MYLES, M.B.; ROCHFORD N. HUNT, M.B., HENRY E. J. A. HOWLEY, RALPH F. M. FAWCETT, WILLIAM L. STEELE, HUGH A. DAVIDSON, M.B.; THOMAS FINUCANE, M.B.; JOHN W. WEST M.B.; WILLIAM RIACH, M.D.; HERBERT R. BATEMAN, HORACE G. PINCHES, THOMAS WHITE, JAMES C. KENNEDY, M.B.; ARTHUR R. C. PARSONS, JOHN B. CAUTLEY, WILLIAM M. B. SPARKES, SAMUEL B. SMITH, M.D.; EYRE W. POWELL, JOHN JONES.

The following are on passage home from South Africa:—Civil Surgeons E. A. Nathan, E. M. Pearce, A. N. Weir, J. A. C. Macewen, G. L. Hadwell, A. C. Robinson, and J. Thomson; Hospital Dresser J. Atkins. For duty on the voyage: Lieutenant-Colonel H. J. Battersby, Civil Surgeons J. A. Barnes, L. Cooper, J. E. Ker.

Civil Surgeon B. A. Nicoll is returning from South Africa invalided.

Civil Surgeon Herbert Hartley, Lovat's Scouts, is returned as convalescent at Capetown.

The following have been discharged from hospital in South Africa to duty: Lieutenant N. J. C. Rutheriord, Civil Surgeon D. W. Johnson, R. Williams, G. L. Hayden, E. H. Worth, A. Young, Major G. A. Wade.

Among the casualties at Nooitgedacht on December 13th, Civil Surgeon Inglebach (? Englebach) is included as missing (believed wounded).

Civil Surgeon Barrett is reported as dangerously ill at Pretoria, December 13th; Civil Surgeon R. M. Cowie, dangerously ill, has slightly improved.

ARMY MEDICAL RESERVE.

SURGEON-MAJOR G. R. T. PHILLIPS is promoted to be Surgeon-Lieutenant-Colonel, December 15th.

Surgeon-Captain T. W. J. ALLEN, having resigned his appointment in the Volunteers, ceases to belong to the Army Medical Reserve, December 15th.

INDIAN MEDICAL SERVICE.

LIEUTENANT-COLONEL J. YOUNG, M.B., Bengal Establishment, is appointed to officiate as Principal Medical Officer Punjab Frontier Force, with the temporary rank of Colonel, from October 8th.

THE MILITIA.

SURGEON-LIEUTENANT-COLONEL J. MUNRO, M.D., 3rd Battalion Durham Light Infantry, resigns his commission on account of ill-health, December 19th; he is permitted to retain his rank and uniform.

MILITIA MEDICAL STAFF CORPS.

SURGEON-CAPTAIN A. R. H. OAKLEY, from the 1st Volunteer Battalion the Essex Regiment, to be Surgeon-Captain, December 19th.

Captain W. V. SINCLAIR, from the 3rd Volunteer Battalion the Devonshire Regiment, to be Surgeon-Lieutenant, December 19th.

Surgeon-Lieutenant W. E. M. CORBETT, from the 2nd Volunteer Bat-

talion the Devonshire Regiment, to be Surgeon-Lieutenant. December 10th.

THE VOLUNTEERS.

SURGEON-MAJOR J. H. WATHEN, 1st Gloucestershire Artillery, resigns his commission, retaining his rank and uniform, December 19th.

CHARLES J. MACALISTER, M.D., formerly Surgeon-Captain 2nd Volunteer Battalion, is appointed Surgeon-Captain in the 8th (Scottish) Volunteer Battalion the King's (Liverpool Regiment), December 5th.

Brigade-Surgeon-Lieutenant-Colonel E. POCKLINGTON, 2nd Volunteer Battalion the East Surrey Regiment, resigns his commission, retaining his rank and uniform, and thereby vacating his appointment as Senior Medical Officer to the Surrey Volunteer Infantry Brigade, December 19th.

Surgeon-Lieutenants L. F. DEMETRIADI and H. W. WILLIAMS, M.B., 2nd Volunteer Battalion the Duke of Wellington's (West Riding Regiment), are promoted to be Surgeon-Captains, December 19th.

Mr. WILLIAM BRATTON is appointed Surgeon Lieutenant in the 2nd Volunteer Battalion the Durham Light Infantry, December 10th.

VOLUNTEER MEDICAL OFFICERS.

VOLUNTEER SURGEON writes: I quite agree with what your correspondent has written *re* volunteer surgeons and expenses; certainly no volunteer surgeon should be expected to subscribe to regimental prize funds, etc.: in fact, the mess subscription should be the only one expected from him. In many regiments, however, where there is an annual subscription to the corps both for officers and men, which does not include the mess subscription, the medical officer is let off the regimental subscription, and is not expected to subscribe to prizes, etc. This is quite right, and should apply to all corps, whether there is an annual regimental subscription or not, for many people quite overlook the fact that a medical man's time is money, and by attending at recruiting hours he often loses patients, which in these days of competition many can ill afford to do. Owing to expenses entailed in being a member of a corps, it is becoming annually harder to get volunteer surgeons. I think that as promotion to the different ranks of volunteer surgeons goes merely as a rule by time, any volunteer surgeon who has served with troops should be promoted more rapidly than in the ordinary course of events, as one month with troops is, from a purely military medical point of view, of greater importance than five years with volunteers; therefore I think that, say, three months with troops ought to be counted as equivalent to one year with volunteers for promotion.

As far as your correspondent's statement goes as to commanding officers sending round circulars to medical officers concerning doing duty at depôts, etc., the matter lies quite in the hands of the volunteer surgeon himself, as he can always refuse to go, except, of course, when the volunteers are mobilised owing to imminent national peril.

WAR OFFICE METHODS OF OBTAINING MILITARY MEDICAL OFFICERS.

M.A.CANT., M.A., M.D.DUBLIN, writes: In your issue of last week you assert in an article anent the employment of civil surgeons that the War Office has made no effort to obtain the services of volunteer medical officers. This assertion is quite contrary to the true state of the case.

In March last (Army Orders 58 and 59) the War Office asked for volunteer surgeons for service abroad and at home, and Army Order 51 March confirmed their eligibility for gratuity under the then existing Article 601 D Royal Warrant for pay, etc.; moreover during the volunteer camps in the summer principal medical officers were instructed when inspecting bearer companies, etc., to ask for volunteers for service under the above-mentioned army orders. It is difficult to conceive what other means—short of dragging the volunteer surgeons forcibly from their homes—the War Office could adopt. The response to this request of the War Office was, I believe of the most meagre description, and it is abundantly proved—as I have pointed out before in answer to rather acrimonious letters from officers of the A.M.R.—that neither they nor officers of the V.M.S. are as a rule available for anything more than aid of a very partial and localised nature. Hence the War Office has had to fall back again on the civil surgeon.

There is no question of "rank"; it is a pity to attempt to raise that "bogy." I have now served continuously for nearly three years, first as a civil surgeon and after as an attached volunteer surgeon, and I have met with nothing but kind consideration from the Army Medical Department and courtesy from general to drummer boy. I cannot conceive any one preferring the dreadful drudgery of general practice to service in the R.A.M.C., and it is my everlasting regret that the age limit prevents my obtaining a commission.

MEDICO-LEGAL AND MEDICO-ETHICAL.

AN ACTION FOR FEES.

BARKER AND JAMES *v.* COXE AND BURNARD.

THIS case was heard before Mr. Justice Wills on December 1st. The action was brought by Dr. R. H. Barker, who practises in partnership with Dr. James at Hungerford, to recover the sum of £201 7s. 6d. for professional services rendered to the late Mr Coxe, of Newbury in Berkshire. A dispute arose as to the sum of £45, the residue of the amount claimed having been paid into court by the defendants, who were the widow and one of the executors of the deceased. The defence was that these charges were unreasonable.

Mr. Atkin appeared for the plaintiffs, Mr. Spokes for the defendants.

According to Dr. Barker's evidence, it appeared that Mr. Coxe had been his patient for over twenty years. In April of the present year Mr. Coxe was suffering from a severe attack of gout and gangrene of the foot. He specially requested the plaintiff to visit him every evening at or after 9 P.M. Dr. Barker lived three and a-half miles from his patient's house. For each of these visits a charge of £2 2s. had been made. In cross-examination, he admitted that he generally charged 10s. 6d. for a daytime visit, and that the deceased had made him a present of £100 shortly before his death.

His Lordship observed that such a gift had nothing whatever to do with the present case.

Dr. Maurice (Marlborough), Dr. Watson, and Dr. Hampshed having given evidence to the effect that the charges were reasonable,

Counsel for the defendants called Dr. Major (Hungerford) and Dr. W. D. Clarke (Newbury), who stated that it was customary to charge a double fee for a night visit, but they admitted there was no invariable rule.

Without calling on counsel for the plaintiffs to reply, his Lordship gave judgment, and said that the reasonableness of a doctor's charges depended upon the circumstances of each case. Here the plaintiff had been requested to attend this patient every night in the week, and in his judgment the charges were reasonable. Judgment for the plaintiff, with costs.

THE FRIENDLY SOCIETIES AND THEIR MEDICAL OFFICERS.

ON account of the unsatisfactory relations which have existed for some time past between friendly societies and the medical profession in many places, the BRITISH MEDICAL JOURNAL has made it a rule to decline all advertisements for such appointments, as only in this way can it avoid occasionally, through ignorance of the local conditions, assisting those who are striving to reduce the medical profession to an unwholesome servitude. But this attitude of the JOURNAL must not be taken to imply any hostility to the friendly societies as a class, and it is certain that in carrying it out advertisements may have to be refused to which there would be no reasonable objection. In too many cases, however, these appointments have been made against the wishes of the local profession, and are filled by men who have not hesitated to defy professional opinion, and from such persons we cannot expect a very high standard of conduct. It is probably of one of these that an anonymous correspondent complains who sends us a circular in which the writer states, "I have resigned the position of senior medical officer to the medical institute held by me for upwards of seven years," and that he intends commencing practice on his own account at — Street on December 4th. The circular goes on to say, "the terms will be just the same as you have been accustomed to," and that "further particulars may be obtained any afternoon or evening at — Street." Such an attempt to prejudice his old employers and to attract to himself the patients with whom he has been brought into relation as medical officer of the medical institute is manifestly improper. It is probable that a remedy for this and other evils would be found by the General Medical Council if a case were properly brought to its notice.

LATENT INSANITY.

AN interesting case from a medico-legal point came before Dr. Danford Thomas, coroner for Central London, at the Paddington Coroner's Court recently. The subject of the inquest was supposed to have committed suicide by inflicting numerous wounds on himself with a razor. According to the brother's evidence the deceased, who resided with him, retired to his bedroom after dinner on the Sunday before his death, and, as he did not come down to tea, the brother went to look for him. He found him on his bed apparently insensible, with blood all over everything. He sent for the police and a doctor, and after their arrival the deceased was removed to St. Mary's Hospital, where he died a week later.

The house-surgeon deposed that on admission the patient had seventy-one wounds on different parts of his body, three being on the throat, but none of them more than skin deep. There was no bleeding when admitted, and he did not think that hæmorrhage had much to do with the death, nor was there anything of a dangerous character in the wounds. The patient was often delirious while in the hospital, and melancholic, and he was of opinion that death was chiefly due to melancholia and asthenia. At the necropsy a dozen lucifer matches were discovered in his stomach, and the liver showed some signs of degenerative changes, such as are common in phosphorus poisoning.

It would be difficult to demonstrate the precise cause of death in this case, but there can be little doubt that the deceased was not of sound mind, and had probably not been so for some time. Notwithstanding, it would have been impossible to have kept him under supervision. The brother stated that beyond being somewhat depressed, the deceased had manifested no sign whatever of mental aberration. He was regular in his habits, able to follow his business, and kept all his accounts with perfect accuracy.

When it is considered that persons of unsound mind are not always content to confine their operations to themselves, it cannot be regarded as good policy to discourage the activity of those officers whose duty it is to administer the lunacy laws, namely, relieving officers and medical practitioners generally. If such officers are to have actions brought against them for the slightest mistakes, it only serves in a Voltairean sense *pour encourager les autres*, even if the defendant eventually wins the action. The victor in a lawsuit seldom has much to congratulate himself about, and it would be far better if the law forbade such actions to be brought except in very exceptional cases. Why should it not be necessary to get the consent of a public functionary who knew something about the difficulties of lunacy practice, such as a Master in Lunacy, before any such action was permitted?

MEDICAL ADVERTISING.

DR. DAVID ANDERSON-[illegible] ciation, I take my turn [illegible] e it is one [illegible] cr- nic[illegible] d Ha[illegible] col[illegible] of Dr [illegible] because his name has appeared too [illegible] in print before the eyes of the public.

At the bottom, wherein does his case differ from the case of the men whose names appear on the enclosed?

That, Sir, is my difficulty. I am no advocate for advertising. Years

ago I stopped my name appearing in the London dailies as appended to bulletins I issued thrice a day when in attendance on a distinguished patient. That is more than some of the members of the Council have done. Are they so hard upon him because he gives his advice for a paltry half-guinea? And dares to call himself a consultant too. That *is* adding insult to injury!

Yet we can never get rid of Nemesis. I have heard sixpenny doctors complain that the competition of the consultants was ruining them. Only one does not call them consultants then, but Surgeon to Saint-this and Physician to Saint-that. And they give their advice for the price of the medicine bottle, the bottle of medicine being thrown in. But that they should be served in a like manner, and their fees (they are now reverentially called *consultants*) cut—why the very thought of it is intolerable!

Perhaps you will solve this difficulty of mine, perhaps you won't, and the Editor's W.P.B. will be its fate. Anyhow, I have for once exercised my privilege and—baited the Editor.

*** Our correspondent does his baiting as Bottom did his roaring, "as gently as any sucking dove.....as 'twere a nightingale." We entirely agree with what we take to be his main contention, that there must not be two rules, one for the consultant and the other for the rest of the profession; but before a man can be blamed because his name appears in the newspapers under circumstances which may suggest advertisement, it is only just to make sure that the advertised one was privy to the advertisement. In the case of one of his enclosures we may feel certain that this condition was not fulfilled. The gratitude of patients sometimes takes forms which are embarrassing to the practitioner, and we conceive the letter in question to be a case in point.

As to the other enclosure, it is an advertisement of a nostrum containing testimonials purporting to have been given by five medical men. In two cases only is the address given, and in neither can we ascertain from the *Medical Register* or the *Medical Directory* that any person of the name given practises at the place mentioned. This leaves three names. Two are fairly common surnames, and occur more than once on the *Medical Register*, but there is no means of identification. The fifth surname does not appear on the *Medical Register* at all. As to three of the five testimonials, therefore, it may be concluded either that the alleged givers are dead or that they never existed. Would it be too optimistic to extend the conclusion to the other two?

We hope that one result of the recent inquiry before the General Medical Council may be to convince everybody that for the honour of the profession all ranks must work together to resist the intrusion of the commercial spirit, with its inevitable sequence—advertising—into professional life.

LIABILITY OF SCHOOL BOARDS FOR MEDICAL ATTENDANCE.

MAC. was asked by the head mistress at a Board school to see a child and "to attend her and the Board would make it right." The accident was of such a nature that in addition to the initial treatment, 23 visits had to be paid, and an account for £2 10s. 6d. was sent in. After six months our correspondent was informed by a member that the Board did not know whether it could or would pay, and that the only reason which led them to entertain the application was that the playground had been neglected and was not safe for children to play in. A little later our correspondent was sent for by the head master to see a boy who had sustained a fracture. Our correspondent gave the necessary treatment and charged £1 1s. He asks whether there can be any doubt about the liability of the School Board.

*** We are advised that the questions raised involve considerable legal difficulty. It is not probable that the members of the School Board would be surcharged in a case of the kind, in respect of any payment made for the first attendance of a medical practitioner, but it is doubtful whether the schoolmistress could pledge the credit of the School Board even to this extent. It is only possible, however, to form an opinion on the point, as no express judicial authority can be found. In the case referred to, the schoolmistress ordered the continuous attendance of our correspondent, and if she did this without the authority of the Board, then, in analogy to the law of principal and agent as established by cases, she may have rendered herself personally responsible, not on the contract, but on her implied promise that she really possessed the authority which she affected to have. The above remarks are apart from any question of negligence on the part of the School Board, in allowing children to play in a playground which is in an unsafe condition. In that case, although as between the medical man and the School Board, the opinion above expressed may in general apply, the parent or next friend of the child might have a right of action on behalf of the child against the School Board, and the fees of the medical practitioner would form part of the damages recoverable. Under the circumstances we would recommend our correspondent to make a formal application to the School Board for payment of the claim, stating that in the event of their declining to pay the amount due, he would have to take legal advice as to his remedy, either against the School Board or personally against the headmistress who authorised his attendance on behalf of the Board. Having regard to the difficult nature of the case, our correspondent should consult a solicitor.

COLLIERY CLUBS.

B. J.—Taking the rate of pay at 2s. 6d. a head for attendance upon accidents only, and, assuming that the number of accidents varied at the different pits from a minimum of 10 per cent. to a maximum of 40 per cent. of the men employed, it is evident that in some pits the pay is satisfactory and in others decidedly the reverse. In the pits where the accidents average 10 per cent. the rate of pay per accident would work out at £1 5s.—a very fair fee. At the pits where the accidents average 40 per cent. the pay per case would only amount to 6s. 3d.—a very inadequate remuneration. The surgeons at these pits are certainly justified in standing out for increased pay, and 15s. a case is not an unfair sum to ask for. But as, judging from the statement before us, "B." bought the practice without knowing anything of the dispute, it seems only fair that he should be given the six months' time he asks for before he is boycotted by his professional neighbours for refusing to fall into line with them. "B." might be advised that the same fee should not necessarily be charged by both old and new societies. It might be based upon the number of accidents occurring at each pit.

THE PURCHASE OF A SHARE IN A PRACTICE.

CIVIS asks whether in negotiating for the purchase of a share in a medical practice it is usual: (1) When the whole purchase money is not paid at once to pay interest on the balance? (2) To bind oneself not to practise within a certain radius on the dissolution of the partnership?

*** Where the agreement is that the whole sum shall be paid down at once there is sometimes a clause that where the purchaser fails to do so he shall as an alternative pay interest at so much per cent. on the balance. Where the agreement is that the purchase money shall be paid in instalments at fixed periods, it is not customary, in the absence of an agreement to the contrary, to pay interest on the unpaid purchase money. It is usual for the vendor of a share in his practice to protect himself by binding the incoming partner not to practise within a certain radius in the event of a dissolution of partnership. The clause is usually mutually binding on either partner leaving the firm.

PERIOD FOR PRESENTATION OF ACCOUNTS.

RURAL writes that there is an impression in his district that accounts for professional services are only valid when rendered within a certain limited time. He would be glad of any information on the subject.

*** It is of no importance legally when the account is rendered, provided that payment is demanded within six years of the debt becoming due. The Statute of Limitations forbids the recovery of all simple contract debts later than six years from the time they first became due, unless the debtor has given a promise to pay in writing before the expiry of that time, or has paid a portion of the debt on account.

NOTIFICATION OF PARTNERSHIP.

A CORRESPONDENT sends us a copy of a lithographed circular notifying the existence of a partnership which he says has been sent only to the medical men practising in the neighbourhood and to the regular patients attended by him during the last twelve or eighteen months. We are of opinion that no objection can be entertained to such a notice circulated under the described limitations.

APPOINTMENTS AND THE SALE OF PRACTICES.

INTEGER asks for an opinion on the following circumstances: X., an old practitioner in a certain district, had in his practice nearly all the clubs and public appointments. X. dies, and his executors seek to sell his practice. Is it in accordance with medical etiquette (1) for any of the other practitioners of the district to apply for the clubs or appointments left vacant by X.'s decease? (2) would the answer be the same if other practitioners are invited to make application by club members and elective bodies? (3) or where the appointments are advertised?

*** There is no breach of professional etiquette in applying for an appointment which is vacant, and the vendor of a practice cannot claim to sell public appointments as part of the same. It is customary, however, to wait till an appointment is advertised, or until candidature is invited by the committee or council with whom the making of the appointment rests.

MIDWIFERY ATTENDANCE.

MEDICAL.—A correspondent writes that he was sent for about 9 P.M. to attend a lady in her confinement. As the pains were spurious he left her, leaving word that he was to be sent for when labour was more advanced. A few days later he heard that his patient had been attended by another medical man. He wishes to know whether he can recover from the husband his fee, one guinea.

*** Yes, if he had been engaged to attend this patient, and in consequence of that engagement visited her on the evening in question. Otherwise, if he was only sent for specially on that occasion to attend, if the labour then came on, he can only recover a fee for his visit and any service he may have then rendered.

THE OBLIGATIONS OF A *LOCUM TENENS*.

HOT WATER.—As we understand that Dr. B. attended Mrs. C. on behalf of Dr. A., he has quite rightly refused to attend Mrs. C. permanently. Had Mrs. C. wished to change her medical attendant she did not go about it the right way. She should have first sent an intimation to Dr. A., and then sought Dr. B.'s services.

FEES FOR CONSULTATIONS.

CAROLUS puts the following cases: (1) A patient of A. is a plaintiff in an action at law. A. certifies that he is unable to attend the court. The defendant requires another practitioner, B., to see the patient and report. B. asks A. to meet him at the patient's house and A. consents, and later B. makes his report. Who is to pay A. his fee for consultation with B.? (2) One of A.'s club patients wishes for a consultation with another practitioner. A. consents, and wishes to know whether he can charge his patient a fee for meeting the consultant, or is the consultation included in the ordinary duties of a club doctor?

*** (1) A.'s patient is responsible for the fee, but if he wins his action, this fee will be included in the costs that the defendant will have to pay. (2) It is no part of the duties of a club doctor to meet a consultant, but if he agrees to do so, he would probably be unable to recover any extra fee for so doing.

MEDICAL ETIQUETTE.

UNCERTAIN asks for an opinion on the following circumstances: A lad, A., is hurt in the employment of his master, B. B. sends for his own doctor, Y., who happened to be out. He then sent for Z., A.'s usual doctor, who attended. Who ought to take charge of A.—Y. or Z.?

*** Z. is entitled to retain the case, unless B. merely asked him to attend in the absence of Y.

ACCIDENTS INSURANCE AND THE WORKMEN'S COMPENSATION ACT.

X. Y. Z.—The scheme referred to in the BRITISH MEDICAL JOURNAL of December 1st is drawn up under Section 111 of the Workmen's Compensation Act. If the Registrar of Friendly Societies, after taking steps to ascertain the views of the employer and workmen, certifies that any scheme of compensation, benefit, or insurance for the workmen of an employer in any employment, whether or not such scheme includes other employers and their workmen, is, on the whole, not less favourable to the general body of workmen and their dependents than the provisions of the Act, the employer may, until the certificate is revoked, contract with any of his workmen that the provisions of the scheme shall be substituted for the provisions of the Act, and thereupon the employer shall be liable only in accordance with the scheme. In the Midlands such a scheme is in force. Contributions are made to a fund by both employers and men, and a society is formed called the South Staffordshire and East Worcestershire Mining District Compensation Fund, which is managed by a joint committee of masters and men. Any information as to the rules and rate of pay could be obtained at the office of the above Society, 267, Castle Street, Dudley, Worcestershire.

THE PUFFING OF MELLIN'S FOOD.

WE are sorry that Mellin's Food Company think it necessary to support the claims of the useful and well-known article they sell by a series of puffing circulars, some of them bordering on the ridiculous, which have been recently sent round to the medical profession. The last of these is one from a doctor who is put down in the *Medical Directory* as "travelling." He finds Mellin's Food useful after brain fag, and after excesses in smoking and alcohol! We hope the writer may be induced to withdraw this circular, as it is most derogatory to the medical profession that puffs of this kind should be permitted to be used for trade advertisements.

UNIVERSITIES AND COLLEGES.

UNIVERSITY OF CAMBRIDGE.

THIRD EXAMINATION FOR MEDICAL AND SURGICAL DEGREES, PART I.—The following candidates have satisfied the Examiners:

Surgery and Midwifery.—H. St. A. Alder, B.A., Pemb.; A. P. M. Anderson, B.A., Trin.; B. L. T. Barnett, M.A., Joh.; J. Barnicot, B.A., Pemb.; A. G. Bate, B.A., King's; S. Bousfield, M.A., Cai.; A. H. Brehaut, B.A., H. Selw.; H. O. Butler, B.A., Emm.; C. de L. Carey, B.A., Emm.; C. J. Coleman, B.A., Trin.; A. J. Fairlie-Clarke, B.A., Emm.; H. Gordon-Smith, B.A., Trin.; A. W. Greig, B.A., Jes.; W. Hill, B.A., Emm.; A. E. Hodder, B.A., King's; E. H. Kitchin, B.A., Down.; J. L. Lock, B.A., Cai.; G. W. Micklethwaite, M.A., Trin.; F. E. Murray, B.A., Joh.; H. Spurrier, B.A., Cai.; J. Stirling-Hamilton, B.A., Jes.; A. H. Style, B.A., Emm.; H. E. Symes-Thompson, M.A., Christ's; A. E. Taylor, B.A., Down.; N. F. Tiechurst, M.A., Cla.; B. L. Thurlow, B.A., Cai.; E. G. Wales, B.A., Down.; F. K. Weaver, B.A., Trin.; H. H. Weir, Trin.

FIRST EXAMINATION FOR MEDICAL AND SURGICAL DEGREES, PART II.—The following candidates have satisfied the Examiners:

Elementary Biology.—A. G. Atkinson, Trin.; G. F. S. Bailey, Cai.; G. B. Bartlett, Sid. Suss.; R. L. Barwick, B.A., Christ's; A. E. Bonny, Sid. Suss.; H. A. Browning, Joh.; R. Burgess, Cai.; A. F. Burton, Christ's; C. St. A. Coles, Trin.; W. D. Coplestone, Jes.; G. W. Craig, Emm.; W. F. Denning, Trin.; G. H. Drew, Christ's; D. Embleton, Christ's; H. J. Gouvain, Joh.; J. L. Graham-Jones, Emm.; F. W. W. Griffin, King's; M. Grundy, Joh.; W. H. Hodgson, Christ's; C. J. R. Hollmeister, Cai.; V. C. Honeybourne, Joh.; N. G. Horner, Cai.; P. P. Laidlaw, Joh.; K. A. Lees, King's; R. B. Lloyd, Emm.; L. H. L. Mackenzie, Trin.; R. M. Miller, B.A., Cla.; H. W. Moxon, Joh.; E. V. Oulton, Christ's; H. A. Pontifex, Pemb.; R. L. Rawlinson, Trin.; E. Sandbach, King's; E. F. Skinner, Corp. Chr.; J. M. Smith, Christ's; B. S. Taylor, M.A., Cla.; C. B. Ticehurst, Joh.; C. H. Treadgold, Cla.; J. A. Venning, Trin.; B. Wahby, Non Coll.; S. L. Walker, Sid. Suss.; D. R. P. Walther, Pemb.; E. G. Wheat, Christ's; A. E. Wilson-Hird, Cla.

FIRST EXAMINATION FOR MEDICAL AND SURGICAL DEGREES, PART I.—The following candidates have satisfied the Examiners:

Chemistry and Physics.—A. G. Atkinson, Trin.; G. F. S. Bailey, Cai.; J. H. Board, Pemb.; S. Churchill, Trin.; E. B. Clayton, Cai.; A. I. Cooke, Cai.; W. D. Coplestone, Jes.; H. B. Corry, Cai.; G. H. Drew, Christ's; H. B. Ellison, Cai.; D. Embleton, Christ's; H. J. Fardon, B.A., Christ's; H. J. Gauvain, Joh.; S. Gooding, Joh.; J. W. Grice, King's; F. W. W. Griffin, King's; M. Grundy, Joh.; T. S. Hele, Emm.; A. L. Hetherington, Trin.; V. C. Honeybourne, Joh.; N. G. Horner, Cai.; C. E. M. Jones, King's; P. P. Laidlaw, Joh.; K. A. Lees, King's; L. F. G. Lewis, Christ's; C. Lillingston, Pemb.; J. W. Linnell, Joh.; P. C. Litchfield, Trin. H.; R. B. Lloyd, Emm.; S. G. Luker, Pemb.; S. G. MacDonald, Joh.; L. H. L. Mackenzie, Trin.; H. W. Moxon, Joh.; H. F. G. Noyes, Cai.; G. G. Packe, Trin.; H. A. Pontifex, Pemb.; J. M. Postlethwaite, Emm.; R. L. Rawlinson, Trin.; E. Sandbach, King's; W. H. Simpson, Cai.; J. M. Smith, Christ's; A. H. C. Suhr, Cai.; W. H. R. Sutton, Down.; R. Svensson, Cai.; H. H. Taylor, Pemb.; C. B. Ticehurst, Joh.; R. Wade, Christ's; S. L. Walker, Sid. Suss.; G. H. H. Waylen, King's; H. P. Weaver, B.A., Trin.; O. K. Wright, Christ's; R. F. Young, Christ's.

Pharmaceutical Chemistry.—E. E. Atkin, Cai.; J. B. Banister, Jes.; S. Barradell-Smith, Joh.; E. Beaton, Cai.; E. M. Brown, B.A., Pemb.; J. W. Chell, Joh.; H. M. Clarke, B.A., Cla.; H. P. Crampton, B.A., Cla.; F. D. Crew, B.A., Emm.; H. M. Davies, B.A. Trin.; C. E. Droop, B.A., Trin.; T. W. Dunn, Cai.; R. G. Elwell, B.A., Trin.; A. H. Fardon, Christ's; J. N. F. Fergusson, Joh.; R. L. Gamlen, Cai.; H. P. B. Gough, Sid. Suss.; W. B. Grandage, Cla.; J. R. C. Greenlees, Joh.; J. M. P. Grell, H. Selw.; C. R. F. Hall, B.A., Trin.; H. S. Hall, Pemb.; A. W. Hayward, Joh.; R. A. P. Hill, Cai.; W. R. Honeyburne, B.A., Pet.; B. L. Hopper, B.A., Cai.; C. W. Hutt, Trin.; J. B. Irving, B.A., Joh.; Q. S. Keat, Joh.; W. D. Keyworth, H. Selw.; B. T. Lang, Trin.; W. Lowe, B.A., Cai.; F. P. Luard, Down.; J. McIntyre, King's; H. F. Marris, B.A., Cai.; A. Morris, B.A., Cai.; T. M. Neatby, M.A., Joh.; F. W. M. Palmer, B.A., Jes.; W. O. Pitt, Emm.; R. Puttock, B.A., Emm.; F. P. Roberts, B.A., Cai.; D. W. Roy, Sid. Sus.; R. B. S. Sewell, Christ's; E. W. Sheaf, B.A., Down.; P. H. Smith, Pemb.; P. L. Stallard, Cai.; B. H. Stewart, B.A., Jes.; C. Strickland, Cai.; D. W. Tacey, B.A., Christ's; R. S. Taylor, Down.; H. A. R. E. Unwin, H. Selw.; H. B. Weir, Trin.; E. Wight, B.A., Sid. Suss.; W. P. Williams, Down.; J. K. Willis, Queen's; L. Worrall, B.A., Christ's.

UNIVERSITY OF DUBLIN.

At the Winter Commencements held on Monday, December 17th, the following Licences and Degrees in Medicine, Surgery, and Midwifery were conferred.

Licentiati in Medicinâ in Chirurgiâ et in Arte Obstetriciâ.—F. J. McAuliffe, F. C. Newland.

Baccalaurei in Medicinâ in Chirurgiâ et in Arte Obstetriciâ.—J. J. Abraham, C. A. K. Ball, C. P. Ball, C. K. Bushe, W. P. Cockle, J. Evans, H. Henry, E. F. Kough, H. W. Long, R. F. Manifold, J. Marnan, T. P. M'Kell, J. B. Meldon, R. W. Mullock, W. C. Oram, M. B. Smyth, J. R. Welland, R. C. Wilson.

Magister in Chirurgiâ.—R. H. Kennan.

Doctores in Medicinâ.—W. P. Cockle, J. Evans, J. J. Long, L. G. A. MacDonnell, J. C. Pounden, T. F. Smith, E. F. Stapleton, J. T. Wigham, R. F. C. Talbot (*in absentiâ*).

Baccalaureus in Medicinâ.—E. R. Chichester (*in absentiâ*).

UNIVERSITY OF ABERDEEN.

ON December 18th, Lord Strathcona, Lord Rector of the University of Aberdeen, delivered his Rectorial Address on the Growth of Imperialism. At the conclusion he offered to contribute £25,000 to the new University scheme, on condition that an additional £50,000 was contributed during the next twelve months.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

AN Ordinary Council was held on December 13th, Sir William MacCormac, Bart., K.C.V.O., President, in the chair.

SECRETARIAL DEPARTMENT.

The Council accepted the resignation of Mr. Edward Trimmer, who will retire in March, 1901, after a service of forty-two years. His successor will be the present Assistant Secretary, Mr. Cowell.

THE LAST ANNUAL MEETING OF FELLOWS AND MEMBERS.

The Council, having fully considered Resolution I moved at the meeting of Fellows and Members on November 15th, 1900, by Dr. H. Snow, M.R.C.S., and seconded by Mr. Joseph Smith, M.R.C.S., and carried *nem. con.*, recorded its opinion that it would be most undesirable to reopen the question of the representation of Members on the Council. The Council also requested the mover and seconder of Resolution II to furnish information as to the points in regard to which they were of opinion that the Medical Acts require amendment. In answer to Resolution III, the Council resolved that the annual report of the Council be sent only to those Fellows and Members who apply for it; but that, to save unnecessary trouble to those who desire to receive the report regularly, any Fellow or Member may on request have his name entered upon a standing list. The fourth resolution, which expressed the opinion that the Council would promote the wider interests of the profession, and would not injure those of this College, by agreeing to the recent recommendations of the General Medical Council with regard to (*a*) the combination with the Apothecaries' Society and (*b*) the question of the commencement of scientific studies, was laid before the Council.

REPORT FROM THE CENTENARY COMMITTEE.

Amongst other details the Committee reported that the cost of the dinner was £606. Towards this £308 was contributed by the subscriptions (two guineas) of those who were present at the dinner, whilst the rest was defrayed by the Council privately—that is, not from the College funds.

COOKE'S SCHOOL OF ANATOMY, ETC.

This was recognised by the Council for another year for the performance of the extra six months' dissection required for the Primary Fellowship Examination.

PROPERTY ADJACENT TO THE COLLEGE.

The President informed the Council that the property extending from Searle Street up to Nos. 35 and 36, Lincoln's Inn Fields, had been acquired by the Crown, and that it was proposed to erect on this site a building projecting beyond the general building line to within 4 feet of the pavement, and he pointed out that such a scheme if carried out would be very injurious to the College buildings and other houses on the south side of Lincoln's Inn Fields, and that, if at any time the Government were to acquire the intervening houses and extend their building on the same lines up to the College premises, serious damage would be caused to the College. The President further stated that he understood the London County Council had requested the First Commissioner of Works to reconsider the matter, and suggested that the Council of the College should take some steps to bring their objections to the proposed scheme under the consideration of the proper authorities. The President was requested to write to the First Commissioner of Works, and ask him to reconsider the matter.

THE LATE MR. HENRY LEE.

A bust of the late Mr. Henry Lee (by Thomas Brock, R.A.) was offered to the College by Mrs. Henry Lee, and accepted by the Council with their best thanks.

ADMISSION TO MEMBERSHIP.

The following gentlemen, having passed the necessary Examinations, have been admitted Members of the College:

H. C. Alderman, Yorkshire College and Royal Infirmary, Leeds; P. F. Alderson, Middlesex Hospital; A. P. M. Anderson and A. de C. Baker, Cambridge University and London Hospital; W. B. Bannerman, London Hospital; D. J. Bedford, Cambridge University, St. Thomas's Hospital and Mason College, Birmingham; H. A. Beetham, Yorkshire College and General Infirmary, Leeds; K. H. Bennett, and S. Breé, University College Hospital; H. A. B. Bransbury, St. George's Hospital; H. Braunt and J. A. Butler, Guy's Hospital; R. H. Botham, King's College Hospital: A. B. Brown and C. R. V. Brown, St. Bartholomew's Hospital; F. E. Brunner, Cambridge University and St. Bartholomew's Hospital; R. S. Burd, Mason University College, Queen's and General Hospital, Birmingham; A. Caddy, St. George's Hospital; P. W. L. Camps, Guy's Hospital; F. C. Carlé, King's College Hospital; H. A. Colwell, St. Bartholomew's Hospital; H. E. Crawley, Oxford University and St. Mary's Hospital; D. M. Davies, St. Mungo's College and London Hospital; W. S. Dickie, St. Mungo's College and Royal Infirmary, Glasgow; R. Dunstan, London Hospital; A. Edmunds, King's College Hospital; F. P. Edwards, Cambridge University and Westminster Hospital; G. D. Edwards, Cambridge, Bristol, and St. George's Hospital; R. A. Facey, P. R. Fort and A. H. Foster, St. Mary's Hospital; G. V. H. Fairhall, Melbourne University and Westminster Hospital; L. P. Farrell, Dalhousie University and University College Hospital; E. H. Felton and D. Forsyth, Guy's Hospital; B. G. Fiddean, University College, Cardiff, and Charing Cross Hospital; W. E. Fisher, University of Dunedin, New Zealand, and University College Hospital: C. H. Francis-Williams, St. George's Hospital; J. S. Gayner, St. Bartholomew's Hospital; K. W. Goadby, Guy's Hospital: L. Gollan, University of Melbourne and St. Mungo's College, Glasgow: E. V. Gostling Cambridge University and St. Thomas's Hospital; J. M. Gover, University of Durham; W. H. C. Greene, Cambridge University and St. Mary's Hospital; W. W. Halsted, St. Thomas's Hospital; G. Hamilton, University of Dunedin, New Zealand, and Middlesex Hospital; H. C. Harrison, Firth College, Sheffield, and St. Bartholomew's Hospital; C. M. Heanley, St. George's Hospital: C. E. Hicks and S. Hodgson, Guy's Hospital; C. E. Hogan, St. Bartholomew's Hospital; E. H. Hogg, Middlesex Hospital; Hugh Hughes, University College and Royal Infirmary, Liverpool; T. H. J. E. Hughes, King's College and St. Mary's Hospital; E. H. Hunt, Oxford University and St. Bartholomew's Hospital: B. F. Hussey, St. Mary's Hospital; R. Jacques, University College, Liverpool, and King's College Hospital; E. A. Johnson, Adelaide and Melbourne University, St. Bartholomew's and London Hospitals; D. M. Johnston, Durham University and St. Bartholomew's Hospital; E. W. J. Ladell, E. V. Lindsey, J. A. Lloyd, and F. H. Lowe, St. Bartholomew's Hospital; P. N. Lakshmanan, University of Madras and King's College Hospital; B. R. Lloyd, University College, Cardiff, and Charing Cross Hospital; R. E. Lloyd, University College Hospital; E. J. Manning, St. Mary's Hospital; J. C. Marshall and S. Mason, St. Bartholomew's Hospital: T. C. Mitchell, Yorkshire College and General Infirmary, Leeds; H. T. Newling, Royal Infirmary, Durham, and St. Mary's Hospital; W. W. Maxwell, Edinburgh University and King's College Hospital; J. C. Newman, Cambridge University and St. Bartholomew's Hospital; J. C. Norton, University College and General Infirmary, Bristol; J. C. Oates, Mason College, Queens and General Infirmary, Birmingham; W. S. Page, St. Mary's Hospital; H. McD. Parrot, Guy's Hospital; E. M. B. Payne, St. Bartholomew's Hospital; J. S. S. Perkins, Cambridge University and Guy's Hospital; P. M. Perkins, Durham University and St. Bartholomew's Hospital; M. H. Phillips, University College and Royal Infirmary, Bristol; L. J. Picton, Oxford University and St. Bartholomew's Hospital: G. W. Procter, Durham University and Middlesex Hospital; J. P. Race, Owens College and Royal Infirmary, Manchester; J. E. Richards, Charing Cross Hospital; B. H. St. C. Roberts, Mason College, Queen's and General Hospital, Birmingham; R. P. Richardson, Durham University and Westminster Hospital; A. R. Roche, Cambridge University and Westminster Hospital; E. N. T. Rogers, Middlesex Hospital; F. C. Rogers, St. Mary's Hospital: W. E. Rutledge and T. C. Savage, University College Hospital: H. Scanlan, McGill College, Montreal, and St. Bartholomew's Hospital; R. W. Shaw, Western University, Ontario and University College; F. W. Sime, Durham University and Guy's Hospital; F. A. Simpson, Cambridge University, St. Mary's and St. George's Hospitals; F. B. Skerrett, Owens College and Royal Infirmary, Manchester, and St. Thomas's Hospital; R. W. I. Smith, Edinburgh University and King's College Hospital; C. D. Soutter, Mason College, Queen's and General Hospitals, Birmingham; H. R. D. Spitta, St. George's Hospital and Durham University; L. E. Stamm, Guy's Hospital; C. M. Stewart, University of Toronto and University College Hospital: F. Stua University of Durham and St. George's Hospital; W. J. Susmann, Cambridge University and St. George's Hospital; J. Tattersall, St. Mary's Hospital; A. J. Tayler, King's College Hospital: E. D. Telford, Cambridge University, Owens College and Royal Infirmary, Manchester; W. M. Thomas, Guy's Hospital; G. W. Thompson, Edinburgh University; R. C. Turnbull. London Hospital: A. R. Tweedie, St. Bartholomew's Hospital; G. A. Upcott-Gill, University College Hospital; C. E. West, Oxford University and St. Bartholomew's Hospital; C. V. White, St. Thomas's Hospital: C. A. Wiggins, St. Mary's Hospital; A. R. B. Williamson, Queen's University, Kingston, Canada; and T. J. White, Guy's Hospital.

ROYAL COLLEGE OF SURGEONS IN IRELAND.

AT a meeting of the Fellows of the College held on Monday, December 17th, Sir William Thomson was unanimously elected a member of the Council.

PUBLIC HEALTH AND POOR-LAW MEDICAL SERVICES.

HEALTH OF ENGLISH TOWNS.

IN thirty-three of the largest English towns, including London, 6,720 births and 3,744 deaths were registered during the week ended Saturday last, December 15th. The annual rate of mortality in these towns, which had been 18.0 and 17.7 per 1,000 in the two preceding weeks, further declined last week to 16.8. The rates in the several towns ranged from 8.6 in Norwich, 11.2 in Oldham, 11.8 in Preston, and 11.9 in Croydon, to 20.0 in Gateshead and in Liverpool, 21.3 in Bolton, 22.1 in Nottingham, and 22.2 in Manchester. In the thirty-two large provincial towns the mean death-rate was 17.0 per 1,000, and exceeded by 0.5 the rate recorded in London, which was 16.5 per 1,000. The zymotic death-rate in the thirty-three towns averaged 1.5 per 1,000; in London this death-rate was equal to 1.2 per 1,000, while it averaged 1.6 in the thirty-two provincial towns, among which the highest zymotic death-rates were 2.4 in Nottingham, 2.5 in Swansea, in Bolton, and in Sunderland, and 3.7 in Sheffield. Measles caused a death-rate of 2.5 in Swansea; whooping-cough of 1.1 in Nottingham, in Sheffield, and in Sunderland; "fever" of 1.3 in Preston; and diarrhœa of 1.3 in Burnley. The death-rate from scarlet fever did not exceed 1.0 in any of the thirty-three large towns. The 77 deaths from diphtheria included 20 in London, 12 in Sheffield, 6 in Leeds, and 6 in Leicester. No fatal case of small-pox was registered last week, either in London or in any of the thirty-two large provincial towns; and only one small-pox patient remained under treatment in the Metropolitan Asylum Hospitals on Saturday last, December 15th. The number of scarlet fever patients in these hospitals and in the London Fever Hospital, which had been 2,727 and 2,687 at the end of the two preceding weeks, had further declined to 2,617 on Saturday last; 255 new cases were admitted during the week, against 246, 279, and 259 in the three preceding weeks.

HEALTH OF SCOTCH TOWNS.

DURING the week ending Saturday last, December 15th, 874 births and 596 deaths were registered in eight of the principal Scotch towns. The annual rate of mortality in these towns, which had been 21.7 and 20.7 per 1,000 in the two preceding weeks, further declined last week to 19.3, but was 2.5 per 1,000 above the mean rate during the same period in the thirty-three large English towns. Among these Scotch towns the death-rates ranged from 16.6 in Leith and 18.1 in Edinburgh, to 19.7 in Glasgow and in Greenock, and 28.7 in Perth. The zymotic death-rate in these towns averaged 2.6 per 1,000, the highest rates being recorded in Aberdeen and Greenock. The 282 deaths registered in Glasgow included 3 from small-pox, 4 from measles, 4 from scarlet fever, 27 from whooping-cough, 4 from "fever," and 4 from diarrhœa. Three fatal cases of measles, and 2 of scarlet fever were recorded in Edinburgh. Nine deaths from measles and 3 from diarrhœa occurred in Aberdeen: and 3 from whooping-cough in Greenock.

ALDERSHOT: HOSPITAL FOR INFECTIOUS DISEASE.

THE Aldershot Council came to a wise conclusion at the meeting held on December 5th, when it decided to proceed at once with the completion of the infectious hospital instead of following the original scheme and building it by degrees. The danger arising from insufficient accommodation for infectious cases at a place like Aldershot is always great; last summer the hospital was overcrowded with 16 cases, and the medical officer had—through lack of a discharging ward—to send patients direct from the infectious wards to their homes. It is satisfactory to learn that, although there was some discussion, the resolution was adopted unanimously.

PROPOSED PUBLIC HEALTH LABORATORY FOR DEVON AND CORNWALL.

IN view of the fact that the "sanitary conscience" of the West of England is not yet awake to the need of county medical officers of health, the action of the Plymouth Town Council, on the advice of the Chairman of the Sanitary Committee, Mr. P. Swain, F.R.C.S., and the Medical Officer of Health for Plymouth, Dr. F. M. Williams, in appointing a "Public Health Laboratory Subcommittee" to promote "the provision of pathological facilities for the examination of infectious disease in the poorer classes, and to obtain the co-operation of the County Councils of Devon and Cornwall in the matter" is the more warmly to be commended.

FOOD EXAMINATION IN BERLIN.

THE establishment of a municipal research office in Berlin for the examination of articles of food is in contemplation. The cost of the building is

estimated at 440,000 marks (£22,000), and that of the installation of the laboratories at 92,000 marks (£4,600); the expense of maintenance is estimated at 23,000 marks (£1,150), while the amount allowed for salaries is 42,160 marks (£2,108). It is somewhat remarkable that although such institutions exist in Saxony, Bavaria, Baden, Hesse, Brunswick, Reuss, and in a number of German cities, as Nürnberg, Hanover, Görlitz, Breslau, Magdeburg, Göttingen, Hildesheim, Emden, Osnabruck, Munster, Frankfurt-on-the-Main, Düsseldorf, Essen, Elberfeld, Barmen, Krefeld, Trier, Koln, Coblenz, Marburg, Wiesbaden, Geisenheim, Bieberich, Halle, Stralsund, and Königsberg, there has hitherto been nothing of the kind in Berlin. At the head of the institute will be a director with a salary of 8,000 marks (£400), and under him a deputy who will be director of the chemical, bacteriological, and physical, microscopic and botanical department with 5,000 marks (£250). There will also be one bacteriological and four chemical assistants.

DISTRICT PAUPER PATIENTS UNDER CARE OF A PRIVATE PRACTITIONER.

RUFUS writes asking what he should do under the following circumstances: Some of my Union patients go a-begging to one lady, who sends them to her own doctor, who takes charge of the cases and treats them. The patients have no complaint to make against me, in fact come and tell me what they have had to do.

*** We should recommend our correspondent to discontinue his attendance while his patients are under the care of another practitioner, but for his own protection to inform them that he will be ready to take up their care again, *if they wish it*, when this ceases.

THE MEDICAL OFFICER OF HEALTH FOR LAMBETH.

Dr. Priestley's salary as Medical Officer of Health has been unanimously increased by £100 per annum by the Lambeth Borough Council.

FEE FOR REDUCTION OF REPEATED DISLOCATION.

"W.," who is a district medical officer, has a pauper patient who has often dislocated his shoulder during an epileptic paroxysm—three times during the past quarter. "W." asks whether he is in order in charging the fee of £1 for each dislocation.

*** We should recommend our correspondent not to make a charge for each dislocation if such should occur more than once in the quarter, and even this if it were to become a regular quarterly claim might give rise to dissatisfaction on the part of the guardians. It would be contended that when the regulations were framed which award a special fee for the reduction of shoulder dislocations it was never intended that they should refer to a case of this description. It should be borne in mind that the Local Government Board have the power, on the application of the guardians, to suspend the action of Article 177 of the Consolidated Order, 1847, if they think fit to do so.

INDIA AND THE COLONIES.

INDIAN REPORTS.

BOMBAY.

Hospitals and Dispensaries.—The report for the year 1898, submitted by Surgeon-General G. Bainbridge, M.D., is bulky. The statistics of the year are contrasted with those of the two preceding years, and thus relate to a period during which an epidemic of plague raged in the Presidency. The Government of Bombay, in a brief note which is appended to the report, comments on the absence of a comprehensive analysis of the effects of the plague epidemic on the administration of the medical institutions in the Mofussil, points out that the report does not include the various temporary plague hospitals which were opened for the treatment of the plague stricken, and shows that the effect of the outbreak has been to diminish the attendance of patients and reduce the number of persons seeking relief for such common maladies as skin diseases and malarious fever. In the report no attempt is made to give a readable account of the state of public health during the period under review, or of the measures and means resorted to for the purposes of medical relief. It is not an administration report, dealing with questions relating to the efficiency, defects, or improvements, actual or possible, of the system of public medical relief, but a dreary mass of figures and facts whose significance and use are buried and concealed by their prolixity or pettiness. The details furnished indicate, however, that the 314 institutions included in the report are doing good work, and are under careful management and supervision.

NORTH-WESTERN PROVINCES AND OUDH.

Dispensaries and Charitable Institutions.—The report for the three years ending December 31st, 1898, submitted by Colonel G. C. Hall, F.R.C.S., is an interesting document indicating progress. The number of institutions was increased by 22, of which 14 were for women. The period was one of famine and plague, and special preventive and relief measures were adopted which interfered with the working of the regular hospitals and dispensaries. The attendance and the number of operations showed a decrease, but there were signs in 1898 of a return to the figures of 1895. The attendance of women and children is growing; this is accepted by the provincial Government as a satisfactory circumstance. A commendable feature in the administration of these hospitals is the provision of special accommodation for Europeans and Eurasians, with the result that increased numbers of these classes are seeking relief. The finances of these institutions are in a satisfactory position, and it is evident that the administration takes a keen interest in them. The report shows that "in the 47 female hospitals of the province there were employed in 1898 19 lady doctors, 33 female hospital assistants, 5 matrons and a staff of 77 nurses, midwives, compounders, and dressers, while 39 female pupils were studying in the Agra medical school, and 33 in other centres." Twenty temporary dispensaries were opened during the year at large fairs and bathing festivals, and there were 32 asylums open for the blind, etc., and lepers.

MEDICAL NEWS.

THE Board of Trade has extended the muzzling order for dogs to the county of Brecon.

THE seventy-third annual congress of the German Scientific and Medical Association will be held at Hamburg in 1901.

DR. W. LESLIE MACKENZIE, who has been appointed an Inspector to the Local Government Board for Scotland, has resigned the post of medical officer to the Leith Town Council. The salary of the vacant office in £400 a year.

A BRONZE relief portrait panel to the memory of the late Samuel Gourley, M.D., F.R.C.S., J.P., has been placed on one of the walls of the Hartlepool Hospital, to which institution he was for twenty-five years honorary surgeon.

IT is announced that Surgeon-Major Reed of the United States army and a board of experts will continue the investigation into the propagation of yellow fever by mosquitos, and an experimental station will be established outside Havana.

IT is proposed to erect a monument in memory of the late Professor Camara Pestana, who fell a victim to his devotion to scientific research in the recent epidemic of plague at Oporto. A considerable sum has already been subscribed for the purpose.

THE honorary medical officers of the Royal Alexandra Hospital for Children, Brighton, recently presented Dr. Edward Mackey with an illuminated address on the occasion of his retirement from the Acting Staff as Senior Physician. Dr. Mackey has been elected one of the Consulting Physicians of the hospital.

DR. MARTIN J. P. DEMPSEY, F.R.C.P.I., Visiting Physician to the Mater Misericordiæ Hospital, Dublin, has been elected to the Chair of Materia Medica and Pharmacy in the Catholic University School of Medicine, rendered vacant by the death of Dr. F. J. B. Quinlan.

A memorial in honour of Bernhard von Langenbeck has been placed by the medical officers of the Prussian army in the great hall of the University of Berlin. It was recently formally handed over by Dr. von Coler, Surgeon-General of the Prussian army, to Professor Harnack, rector of the University.

PROPOSED HOSPITAL FOR PUTNEY.—Mr. Henry Chester, of Putney Hill, who died on October 23rd last, left a sum of money to the Haberdashers' Company of London, to be by it applied to the sustentation of a hospital, should such an institution be established in Putney. He directed that until such hospital has been established the income should be accumulated by investments, and if no hospital be erected and opened within twenty years, the income is thereafter to be paid to Guy's Hospital. It is stated that the amount available at present is about £60,000.

MEDICAL VACANCIES.

The following vacancies are announced:

BIRMINGHAM: GENERAL HOSPITAL.—Two Casualty Assistant Physicians. Appointments for one year, but eligible for re-election. Salary, £50 per annum. Applications to the House Governor by December 28th.

BOURNEMOUTH: ROYAL BOSCOMBE AND WEST HANTS HOSPITAL.—House-Surgeon. Salary, £60 per annum, with board, lodging, and washing. Applications to the Secretary by January 1st, 1901.

BRIGHTON, HOVE, AND PRESTON DISPENSARY.—Three House-Surgeons. Salary, £160 per annum, with furnished apartments, etc. Applications to the Assistant Secretary, 113, Queen's Road, Brighton, by December 27th.

BRIGHTON: SUSSEX COUNTY HOSPITAL.—(1) Second House-Surgeon and Anæsthetist. Salary, £70 per annum. (2) Third House-Surgeon. Salary, £60 per annum. Candidates must be unmarried. Board and residence provided in each case. Applications to the Secretary by December 26th.

CHELSEA, BROMPTON, AND BELGRAVE DISPENSARY, Sloane Square, S.W.—Surgeon. Applications to the Secretary by December 31st.

CHELTENHAM GENERAL HOSPITAL.—Junior House-Surgeon, unmarried. Salary, £45 per annum, with board, lodging, and washing. Applications to the Honorary Secretary by January 5th, 1901.

CHESTER GENERAL INFIRMARY.—Second Resident Medical Officer. Salary, £80 per annum, with residence and maintenance. Applications to the Chairman of the Board of Management, 29, Eastgate Row North, Chester, by December 31st.

CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST, Victoria Park, E.—House-Physician. Appointment for six months. Salary at the rate of £30 per annum, with board and residence. Applications to the Secretary before January 7th, 1901.

DERBYSHIRE ROYAL INFIRMARY.—Honorary Physician. Applications to the Secretary by December 26th.

DONCASTER GENERAL INFIRMARY AND DISPENSARY.—Assistant House-Surgeon. Salary, £50 per annum, with board and residence. Applications to the Honorary secretary by January 3rd, 1901.

DUDLEY: GUEST HOSPITAL.—Senior Resident Medical Officer. Salary, £100 per annum, increasing to £120, with board, residence, attendance, and washing. Applications to the Secretary by January 10th, 1901.

EAST LONDON HOSPITAL FOR CHILDREN, Shadwell, E.—Pathologist and Registrar. Applications to the Secretary by January 15th, 1901.

EDINBURGH UNIVERSITY.—Additional Examiner in the following departments: (1) Pathology, (2) Surgery, (3) Practice of Medicine, (4) Clinical Medicine, (5) Midwifery, (6) Physiology, (7) Anatomy, including Anthropology, (8) Medical Jurisprudence and Public Health and Sanitation, Sanitary Law, and Vital Statistics, (9) Public Health Laboratory Work, (10) Chemistry, (11) Botany. Applications to the Secretary, University Courts, University of Edinburgh, by January 8th, 1901.

HOSPITAL FOR WOMEN, Soho Square, W.—(1) Assistant Surgeon, must be F.R.C.S. Eng. (2) Assistant Physician. Applications to the Secretary for (1) by December 20th, and for (2) by January 5th, 1901.

HULL ROYAL INFIRMARY.—(1 Junior Assistant House-Surgeon. Salary, £40 per annum, with board and lodging. (2) Honorary Assistant Surgeon for Out-patient Department. Applications for (1) to the Chairman, House Committee, by December 24th; for (2) to the Chairman, Committee of Management, by January 2nd.

KENT COUNTY ASYLUM, Barming Heath, Maidstone.—Fourth Assistant Medical Officer and Pathologist. Salary, £175 per annum, rising £5 a year, with furnished quarters, etc. Applications to Dr. F. Pritchard-Davies, Superintendent, by January 12th, 1901.

KIMBERLEY BOARD OF HEALTH.—Medical Officer. Salary, £750 per annum with allowance of £5 per month for horse-keep. Applications to "The Secretary Kimberley Board of Health, care of the Agent-General for the Cape of Good Hope, 112, Victoria Street, London, S.W.," by December 28th.

LANCASHIRE COUNTY ASYLUM, Whittingham.—Junior Assistant Medical Officer, unmarried, and not over 30 years of age. Salary, £150 per annum increasing to £200, and on promotion to £250, with furnished apartments, board, washing, and attendance. Applications to the Medical Superintendent.

LEEDS PUBLIC DISPENSARY.—Two Junior Resident Medical Officers. Salary, £100 per annum, increasing by £10 on reappointment, with board and lodging. Applications to the Secretary of the Faculty.

LEICESTER INFIRMARY.—House-Physician. Salary, £100 per annum, with board, apartments, and washing. Applications to the Secretary, 24, Friar Lane, Leicester, by January 5th, 1901.

LEITH BURGH.—Medical Officer of Health. Salary, £400 per annum. Application to the Town Clerk, Leith, by January 7th, 1901.

LIVERPOOL DISPENSARIES.—Assistant Surgeon, unmarried. Salary, £100 per annum, with board and apartments. Applications to Mr. R. R. Greene, Secretary, Leith Offices, Liverpool.

LIVERPOOL STANLEY HOSPITAL.—Senior House-Surgeon. Salary, £70 per annum, with board, residence, and washing. Applications to the Chairman of the Medical Board by December 27th.

LONDON THROAT HOSPITAL, Great Portland Street, W.—Assistant Surgeon. Applications to the Honorary Secretary, Medical Committee by January 12th.

MANCHESTER: ANCOATS HOSPITAL.—Resident House-Physician. Salary, £80 per annum, with board, etc. Applications to the Secretary.

MARGATE: ROYAL SEA BATHING HOSPITAL.—Assistant Resident Surgeon. Salary, £52 per annum, with board and residence. Applications to the Secretary at the offices, 30, Charing Cross, London, S.W., by January 19th, 1901.

METROPOLITAN ASYLUMS BOARD.—Assistant Medical Officer for the Asylum for Imbeciles at Caterham. Unmarried, and not exceeding 35 years of age. Salary, £150, rising to £170, with rations, lodging, attendance, and washing. Applications on forms provided to be sent to the office of the Board, Victoria Embankment, E.C., by January 5th.

MILLER HOSPITAL AND ROYAL KENT DISPENSARY, Greenwich Road, S.E.—Junior Resident Medical Officer. Appointment for six months, with prospect of re-election as Senior. Salary, £60 per annum, with board, attendance, and washing. Applications to the Secretary by December 31st.

NORFOLK COUNTY ASYLUM, Thorpe, Norwich.—Junior Assistant Medical Officer, not exceeding 30 years of age. Salary, £120 per annum, rising to £150, with board, lodging, and washing. Applications to the Medical Superintendent.

NOTTINGHAM GENERAL DISPENSARY.—Assistant Resident Surgeon; unmarried. Salary, £140 per annum, and all found except board. Applications to the Secretary.

OXFORD: RADCLIFFE INFIRMARY.—Honorary Assistant Surgeon. Applications to the Secretary by January 16th, 1901.

PARTICK BURGH.—Medical Officer, to act also as Casualty Surgeon. Salary proposed, £150 per annum. Applications to Mr. J. Donaldson, Clerk to the Commissioners, Burgh Chambers, Partick, Glasgow, by December 23th.

PORTSMOUTH: ROYAL PORTSMOUTH, PORTSEA, AND GOSPORT HOSPITAL.—House-Surgeon; unmarried. Salary, £100 per annum, with board and residence. Applications to the Secretary by December 27th.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.—Member of the Court of Examiners. Applications to the Secretary.

ROYAL HOSPITAL FOR CHILDREN AND WOMEN, Waterloo Bridge Road, S.E.—Assistant Surgeon, must be F.R.C.S.Eng. Applications to the Secretary by December 28th.

SALFORD UNION.—Assistant Medical Officer at the Union Infirmary, Hope, near Eccles. Salary, £150 per annum with apartments and attendance. Applications endorsed "Assistant Medical Officer," to the Clerk to the Guardians, Union Offices, Eccles New Road, Salford, by January 9th, 1901.

SALISBURY FISHERTON HILL ASYLUM.—Assistant Medical Officer, unmarried, and not more than 30 years of age. Salary, £150 per annum, with board, lodging, and washing. Applications to Dr. Finch.

STOKE-UPON-TRENT: NORTH STAFFORDSHIRE INFIRMARY, Hartshill.—Assistant House-Surgeon. Appointment for six months. Board, apartments, and washing, and an honorarium of not less than £10. Applications to the Secretary by December 27th.

SHREWSBURY: SALOP INFIRMARY.—House-Surgeon. Salary, £110 per annum, with board, washing, and residence. Applications to the Board of Directors by December 28th.

SUNDERLAND: MONKWEARMOUTH AND SOUTHWICK HOSPITAL.—House-Surgeon; unmarried. Salary, £80 per annum with board, residence, and washing. Applications to the Honorary Secretary by January 5th, 1901.

SWANSEA GENERAL AND EYE HOSPITAL.—House-Physician. Salary, £75 per annum, with board, apartments, and washing. Applications to the Secretary by December 24th.

TAUNTON: TAUNTON AND SOMERSET HOSPITAL.—Assistant House-Surgeon. Appointment for six months. Salary at the rate of £60 per annum, with board, lodging, and laundry. Applications to the Honorary Secretary.

VICTORIA HOSPITAL FOR CHILDREN, Queen's Road, S.W.—House-Surgeon. Appointment for six months. Honorarium, £25, with board and lodging. Applications to the Secretary by December 20th.

WESTERN GENERAL DISPENSARY, Marylebone Road.—Two Honorary Surgeons. Applications to the Honorary Secretary.

WEST LONDON HOSPITAL, Hammersmith Road, W.—(1) House-Physician, (2) House-Surgeon. Appointments for six months. Board and lodging provided in each case. Applications to the Secretary by December 26th.

WOLVERHAMPTON AND STAFFORDSHIRE GENERAL HOSPITAL.—Assistant House-Surgeon. Appointment for six months. Honorarium at the rate of £75 per annum, with board, lodging, and washing. Applications to the Chairman of the Medical Committee by January 3rd, 1901.

WORKSOP DISPENSARY AND VICTORIA HOSPITAL.—House-Surgeon and Dispenser. Salary, £150 per annum, with rooms and attendance. Applications to Mr. C. A. Whall, 44, Bridge Street, Worksop.

MEDICAL APPOINTMENTS.

BARCLAY, W. J., M.B., Ch.B., appointed Resident Medical Assistant at the Dundee Infirmary.

BODMAN, C. Osmond, M.B., B.S.Durh., M.R.C.S.Eng., L.R.C.P.Lond., appointed Resident Medical Officer to the Royal Hospital for Children and Women, Waterloo Bridge Road.

BRADFORD, W. G. H., B.A., M.B., B.C.Cantab., appointed Medical Officer and Public Vaccinator for the Debenham District of the Bosmere and Claydon Union.

DE SYLVA, Elph. J., B.A., L.R.C.P.Edin., L. & C.S.Edin., L.F.P.Glasg., appointed Medical Officer to the Parish of Lingwall, Whiteness and Weisdale, Shetland Islands.

DEY, Robert, M.B.Syd., appointed Government Medical Officer and Vaccinator at Wagga Wagga, New South Wales.

DINSMORE, Geo. H. J., M.B., C.M., appointed Medical Officer for the Eccles Parish Workhouse, Berwickshire.

ENSOR, C. A., M.R.C.S., L.R.C.P., appointed District Medical Officer and Medical Officer of the Workhouse of the Tisbury Union, *vice* J. A. Ensor, M.R.C.S.Eng.

FLACK, Frederick Henry, M.B., Ch.B.Vict. Univ., appointed Junior House-Surgeon to the Blackburn and East Lancashire Infirmary.

FREYER, John K., L.R.C.S., L.R.C.P.Irel., appointed Government Medical Officer and Vaccinator at Campbelltown, New South Wales.

GOSTLING, E. Victor, M.R.C.S., L.R.C.P., appointed House-Physician to the Derbyshire Royal Infirmary.

HARRISON, Edward M.A., M.D.Cantab., F.R.C.S.Eng., appointed Honorary Surgeon to the Hull Royal Infirmary.

HEPBURN, Malcolm L., M.D., B.S., F.R.C.S., appointed Surgeon to the Lowestoft Hospital.

HUNT, James S., M.R.C.S.Eng., L.R.C.P.Edin., appointed Superintendent of the Institution for Inebriates at the Dunwich Benevolent Asylum, Queensland.

HUTCHENS, Harold J., appointed Medical Officer of Health to the Joint Board for the Prevention of Epidemic Diseases, Brisbane, and to continue to act as Medical Superintendent of the Plague Hospital.

JOYCE, Caleb, M.B.Melb., appointed Health Officer to the Beaconsfield Board of Health, Tasmania.

KILVERT, J. Ellis, M.R.C.S., L.R.C.P., appointed House-Surgeon to the Derbyshire Royal Infirmary.

LESCHEN, Henry A., M.B., Ch.M.Edin., appointed Medical Superintendent at the Whitby Falls Lunatic Asylum, West Australia.

MCDOUALL, Herbert C., M.R.C.S., L.R.C.P.Lond., appointed Senior Medical Officer at the Hospital for Insane, Callan Park, New South Wales, *vice* R. J. Millard, M.B., Ch.M.Syd.

MACKIE, William James, M.D.Brux., L.R.C.S., L.R.Q.C.P.Irel., appointed Medical Officer of the Lunatic Asylum, Nelson, New Zealand.

MONTGOMERY, W. P., M.A.Oxon., M.R. and B.S.Lond., F.R.C.S., appointed Assistant Surgeon to the Manchester Children's Hospital.

NEWMAN, G., M.D.Edin., D.P.H.Camb., appointed Medical Officer of Health for the Borough of Finsbury.

RICE George, M.D.Durh., appointed Honorary Physician to the Derbyshire Royal Infirmary, *vice* C. A. Greaves, M.B.Lond., resigned.

ROBINSON, Arthur, M.D.Edin., appointed Professor of Anatomy at King's College, London.

SHAW, John C., M.R.C.S., L.R.C.P., appointed Surgeon to the Royal Far Hospital, Soho.

SOUTHERN, J. Acton, M.R.C.S., L.R.C.P., appointed Honorary Surgeon to the Derbyshire Royal Infirmary, *vice* W. Grafton Carpenter, M.D.St. And., resigned.

TURNER, J. A., M.B., C.M.Edin., D.P.H.Camb., appointed Executive Health Officer of Bombay.

BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths is 3s. 6d., which sum should be forwarded in post-office order or stamps with the notice not later than Wednesday morning, in order to ensure insertion in the current issue.

MARRIAGES.

BENNETT—TANGYE.—On December 18th, at Carr's Lane Chapel, Birmingham, by the Rev. J. H. Jowett, W. E. Bennett, F.R.C.S., of 22, Broad Street, Birmingham, son of Wm. Bennett, Hertford Place, Coventry, to Mary Ethel Tangye, only daughter of George Tangye, J.P., of Heathfield Hall, Handsworth, Birmingham.

DAWSON—YARROW.—On December 18th, at St. James's Church, Kidbrook, Blackheath, by the Rev. L. Dawson, brother of the bridegroom, assisted by the Rev. F. Wainwright and the Rev. Canon Leeke (Vicar), Bertrand Dawson, M.D., son of Henry Dawson, of Purley, to Minnie Ethel, youngest daughter of A. F. Yarrow, of Woodlands, Blackheath.

LINNGTON—SIMS.—On December 15th, at All Saints, Norfolk Square, W., by the Rev. William Boyd, M.A., William West Linington, F.R.C.S.Eng., of Folkestone, son of the Rev. W. A. Linington, Nightingale Lane, S.W., to Nina Sims, the eldest daughter of Charles Sims, Esq., L.D.S.Eng., of Edgbaston.

SHAW—WATHEN.—On December 15th, at St. Mary's Church, Westerham, by the Rev. W. M. H. Wathen, brother of the bride, assisted by the Rev. S. Le Mesurier, Vicar of the Parish, Cecil Edward Shaw, M.D., youngest son of the late Rev. George Shaw, Belfast, to Agnes Lascelles Wathen, fourth daughter of William Hulbert and Katharine Cadogan Wathen, of Westerham.

DEATH.

BRAINE.—On December 18th, at 67, Wimpole Street, W., Hannah Elizabeth, the beloved wife of Woodhouse Braine, F.R.C.S.

HOURS OF ATTENDANCE AND OPERATION DAYS AT THE LONDON HOSPITALS.

CANCER, Brompton (Free). *Attendances.*—Daily, 2. *Operations.*—Tu. W. F., 2.
CENTRAL LONDON OPHTHALMIC. *Attendances.*—Daily, 1. *Operations.*—Daily.
CENTRAL LONDON THROAT, NOSE, AND EAR. *Attendances.*—M. W. Th. S., 2; Tu F., 5. *Operations.*—1.p., Tu., 2.30; o.p., F., 2.

LETTERS, NOTES, AND ANSWERS TO CORRESPONDENTS.

COMMUNICATIONS FOR THE CURRENT WEEK'S JOURNAL SHOULD REACH THE OFFICE NOT LATER THAN MIDDAY ON WEDNESDAY. TELEGRAMS CAN BE RECEIVED ON THURSDAY MORNING.

COMMUNICATIONS respecting Editorial matters should be addressed to the Editor, 1, Agar Street, Strand, W.C., London; those concerning business matters, advertisements, non-delivery of the JOURNAL, etc., should be addressed to the Manager, at the Office, 429, Strand, W.C., London.

ORIGINAL ARTICLES and LETTERS *forwarded for publication are understood to be offered to the* BRITISH MEDICAL JOURNAL *alone, unless the contrary be stated.*

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Manager, 429, Strand, W.C., on receipt of proof.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

CORRESPONDENTS not answered are requested to look at the Notices to Correspondents of the following week.

MANUSCRIPTS FORWARDED TO THE OFFICE OF THIS JOURNAL CANNOT UNDER ANY CIRCUMSTANCES BE RETURNED.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL, and not at his private house.

TELEGRAPHIC ADDRESS.—The telegraphic address of the EDITOR of the BRITISH MEDICAL JOURNAL is *Aitiology, London.* The telegraphic address of the MANAGER of the BRITISH MEDICAL JOURNAL is *Articulate, London.*

☞ *Queries, answers, and communications relating to subjects to which special departments of the* BRITISH MEDICAL JOURNAL *are devoted will be found under their respective headings.*

QUERIES.

PROLONGED USE OF SACCHARIN.

ALPHA asks whether any ill effects—such as digestive trouble more especially—have been noticed in connection with the prolonged use of saccharin, say for three or four years, as a substitute for sugar.

DISTRICT NURSES.

A CORRESPONDENT writes that a local district nursing fund has a nurse who has undergone a certain amount of training in midwifery. Up to the present she has not been permitted to attend any patient not under the charge of a registered practitioner. Owing to this restriction, the committee finds that the poorest class will not employ her, but avail themselves instead of an ignorant midwife. Under these circumstances would the medical men of the district be justified in consenting to go and assist the nurse, if she got into any difficulty, while attending to a case where no medical practitioner was in charge?

*** As the medical practitioners would attend to a case in which a midwife had got into difficulties, they would no doubt do the same in the case of the nurse. None the less, it is incumbent on all medical practitioners to discourage the practice of allowing nurses to act except under the direct supervision of a medical man. The more respectable nursing institutes nearly always forbid their nurses to accept any cases not in charge of a medical attendant, and such a regulation is deserving of all respect.

ANSWERS.

G. B.—Our Berlin correspondent informs us that there are no regulations which would prohibit a Chinaman studying and taking a degree either at Freiburg or at Heidelberg University.

LA ROCHE.—Candidates for both the L.M.S. and R.A.M.C., who take up French or German as voluntary subjects, are given an English passage for translation.

HERNIA.—(1) We do not know of any institution where a fully-trained nurse could receive instruction in monthly nursing for so short a period as a fortnight; (2) in the case of a non virgin the finding of spermatozoa in the vagina alone would prove the occurrence of recent connection.

H. S. G.—One of the most comprehensive works upon pathological anatomy is that by Ziegler. The last edition is in two parts—general and special; the latter part is translated into English and published by Macmillan (1896); no translation of the former part has yet appeared; the translation of an earlier edition was published in 1885. This work includes a large amount of histology, but perhaps Weichselbaum's *Elements of Pathological Histology*, translated by Dawson and published by Longmans, Green and Co. (1895), would also be useful.

MEDICAL BOOK-KEEPING.

BOTH Dr. Rowthorn and Dr. Hugh Heald, who in the BRITISH MEDICAL JOURNAL of December 16th answered a question with regard to medical bookkeeping, ask us to state that they have received so many requests for further particulars that they find themselves quite unable to answer all the inquiries by private letter. We propose, therefore, to publish some particulars with which they have been good enough to offer to supply us, but regret that some slight delay must inevitably occur in doing this.

DR. GEORGE BIRT (Stourbridge) writes in answer to "C." in the BRITISH MEDICAL JOURNAL of December 1st, p. 1623:—As I have neither partner, assistant, nor dispenser, I have kept my books with as little trouble to myself as possible for the past 20 years. I buy a 5s. ledger and index it throughout by gumming strips of tracing cloth, on each of which I have written a letter of the alphabet, so that the letter projects beyond the page, and I can open the ledger at any letter required in a moment. I find half a page is quite enough to enter the attendance on a small family for a year. I enter the items in brief—for example, "V" signifies visit, and I use contractions for the prescriptions. I have no daybook, but use a Smith's visiting list. The first week or two in the year the writing is rather heavy, as there are so many new entries to be made; but after that, it does not take long to enter the day's work, and the account is always "posted up" and can be "priced" at any time, and one sees at a glance what the medical treatment has been. I gum the A slip on the first page, B on page 18 C 62, D 100, E 118, F 132, G 144, H 168, J 216, K 230, L 248, M 266, N 292, O 304, P 316, Q 356, R 358, S 380, T 420, V 444, W 464, Y 498.

NOTES, LETTERS, ETC.

THE APPEAL ON BEHALF OF THE WIDOW AND FAMILY OF THE LATE DR. QUINLIVAN.

THE following additional subscriptions have been received towards this fund, the objects of which were fully stated in the BRITISH MEDICAL JOURNAL of November 7th, 1900, p. 1450:

	£	s.	d.
Mr. and Mrs. F. J. Hamly	1	1	0
Dr. Guisani	1	0	0
Dr. Lohane	1	1	0
Dr. Dunn	0	10	6
Total	3	12	6

THE DEATH OF SENTIMENTAL TOMMY.

"LADY PIPPINWORTH" writes: I am exceedingly obliged to Dr. Campbell Highet for his letter on the above subject in the BRITISH MEDICAL

JOURNAL of December 15th, and for the case which he submits "as testimony of his belief in the reasonableness of Mr. Barrie's story." But after a careful consideration of the same, I am reluctantly forced to the conclusion either that Dr. Highet has not read the book or the extract embodied in my letter, or that he utterly fails to comprehend "the peculiar manner in which Mr. J. M. Barrie puts an end to the life of Tommy in his book *Tommy and Grisel*." There is little or no analogy between the case quoted by Dr. Campbell Highet and that of Mr. Barrie's hero. To begin with, there is the difference between the little boy of 4 and the grown man, Tommy. Again, the boy with his feet on the lowest bar of the gate thrust his head between two of the upper bars; away go his feet from the banging of the gate, and it is not difficult to see how the fatal result comes about, as Dr. Campbell Highet says the larynx was tightly compressed, and the child dies from suffocation. It is hardly necessary for him to add "that he seems not to have had the presence of mind to use his hands to raise his body, or that if he had his weight and the fright rendered his arms powerless for good." He was only 4 years old, poor child, and he probably kicked with his legs and hastened his death. This is as plain as the proverbial mud in a wine glass. But it was not so with Tommy. He was climbing a wall, and "as he was descending, one of the iron spikes on the top of it pierced his coat, which was buttoned to the throat, and he hung there by the neck. He struggled as he choked," the first and only point in common between Tommy and the poor Dalmellington boy—"but he could not help himself." In all seriousness, I want to know why? What on earth was there to hinder Tommy using his hands to unbutton the old doctor's coat? He was not a child of 4, and the operation, one would think, would be a simple and an easy one. Must we conclude that his presence of mind failed him, or that his fright rendered his arms powerless for good? For my part, I decline to have Tommy's death laid at my door. I am willing enough to believe, if you like, that Tommy committed suicide, but I can honestly say that no real blame for this rests with me.

THE MEDICAL SITUATION.

DR. THOMAS LAFFAN (Cashel) writes: Earnestly would I ask my provincial brethren to take a survey of the present medical situation. Many of them have sons for instance. How do they like being deprived of the power to give those sons so much as a petty vaccination certificate? They cannot take an apprentice either within or without their own families, though the visitors of the General Medical Council have reported that the clinical material now made use of is not sufficient for teaching purposes. We know how the General Medical Council have acted in the matter of apprenticeships. Driven to re-establish it they deliberately did it in such a way as to render the whole thing nugatory. I wanted myself to train a midwife in my hospital, but having got a private tip from headquarters that metropolitanism alone could be entrusted with so awful a responsibility, was fain to drop the project like a red-hot coal. All nurses can only be trained in the very places where the General Medical Council visitors tell us there is not material enough to train the students. The results are that half of them only receive a mock training, and that twice the amount of salary has to be paid them above what should be legitimate. Midwives determine who is to have the practice in a given locality. They do not confine themselves to natural cases, and I say that the Dublin examining bodies encourage them to do so by never exercising any control whatever over them. The profession, in point of fact, consists of two elements—the ruling few and the plundered many. The ruling few scoop all they can out of us as students and then plunder us of all our patients by converting their hospitals into hotels for unscrupulous rural knaves. There will be an election in February for a direct representative. Will some rural practitioner come forward who belongs to the masses—that is, to the plundered many—and who is, therefore, wholly unconnected with school or licensing body? And I for one will give him my hearty support if he will pledge himself to vote for the following:

1. Reform of the General Medical Council, so that the representative of each body on that Council shall be elected by the entire constituency only of the medical graduates or medical licentiates of such body.

2. That he will vote for the introduction of the competitive system into all branches of the public medical service.

3. That he will vote to put down all breaches of the medical curriculum which allow persons who are engaged in other avocations during each day to obtain fraudulent entrance into the profession.

4. That he will vote to put down back-door entrances to the profession in the shape of special stated or private examinations, and that he will insist that every member of the profession shall have access to every examination, and shall be even allowed to employ shorthand reporters to take down questions and replies.

5. That he will re-establish apprenticeships and utilise provincial hospitals for teaching purposes.

6. That he will vote for compulsory and national superannuation, and for fixity of tenure in the Poor-law service in Ireland.

THE CAUSATION OF SEX.

MR. THOMAS TUCKEY (Fowey) writes: Long ago, in my lamb and salad days, I furnished an article to one of the medical periodicals bearing on the determination of sex, and bringing forward the same theory as Dr. Rumley Dawson (BRITISH MEDICAL JOURNAL, December 15th, p. 1760). Some weeks afterwards I received a letter from a celebrated American ovariotomist, dated from New York, politely informing me that I was labouring under a misapprehension. He sent me statistics of many cases where my theory did not hold good; these statistics I have unfortunately lost, but they were convincing to the last degree. Sir John Falstaff, you may remember, had his own theory on the subject, and stated that milk and water fellows generally breed girls. This is contrary to my experience. Thus taking 150 first cases from my midwifery case book I find that of these 69 were males and 81 females. Of course the next 150 might reverse the proportion, but I think these 150 are fairly representative. Thus we see in first children, where the parents are generally young, the woman unexhausted and fresh, and the man not worn out by toil or other debilitating influences, there are twelve more female than male children. As far as my experience goes, I have often seen several female children at first and then the long-expected son and heir. We know that among insects, bees, ants, etc., the sex of the grub is determined by the amount of food, and that on the loss of the grub which is to become the queen, the working bees can produce another queen by feeding up a grub which with less nourishment would become a worker—that is, an undeveloped sexual individual. There is a deep physiological fact behind the Irish skit of the squire's wife who was lamenting to her labourer's wife that she had no son, while the labourer's wife had several. "Try potatoes, ma'm," advised the peasant. In feeding and the relative strength of man and woman, I think, lies the secret of sexual development, and not in the presence or absence of either ovary.

LETTERS, COMMUNICATIONS, ETC., have been received from

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

Eight lines and under	£0 4 0
Each additional line	0 0 6
A whole column	1 17 6
A page	5 5 0

An average line contains six words.

Advertisements should be delivered, addressed to the Manager, at the Office, not later than first post on Wednesday morning preceding publication; and if not paid for at the time, should be accompanied by a reference.

Post-Office Orders should be made payable to the British Medical Association at the General Post-Office, London. Small amounts may be paid in postage-stamps.

N.B.—It is against the rules of the Post Office to receive letters at *Poste Restantes* addressed either in initials or numbers.

A Century's Retrospect of Medicine

1800—1900

Introduction

IT SEEMS fitting that in the issue of the BRITISH MEDICAL JOURNAL for December 29th, 1900, the last which will appear in the nineteenth century, some note should be taken of the passing epoch, and some attempt made to indicate what has been gained for medicine in the century which is drawing so rapidly to a close.

Many retrospective articles and addresses tracing the course and the sources of this progress have already been published, and to attempt to repeat the story would be to tell a tale already well told. The BRITISH MEDICAL JOURNAL may be the more readily excused from attempting the task, because the special "Queen's Commemoration Number," published on June 19th, 1897, on the occasion of the completion of the sixtieth year of the Queen's reign, dealt fully and systematically with the progress made in that part of the century during which the forward movement proceeded at an ever-accelerating pace.

It has been thought, however, that it would be interesting to try to show what was being taught to students of medicine in the schools of Great Britain and Ireland in or about the first year of this century, and to compare it with what is being taught in this last year of the century, and to indicate also how far the manners of that date and the customs and general conditions of life affecting the health of the community differed from those of the present day when we stand on the threshold of a new century, as did our forefathers in 1800.

But before passing to the articles which we owe to the kindness of a number of members of the profession who will be recognised as by their studies especially competent to deal with the several departments, it may be well to glance at the general position of affairs in 1800.

The third George was king, and the egregious Pye, his poet laureate, had that year, in a birthday ode, which ended with a new version of the National Anthem, called on Heaven for "awful justice red" against the world at large:

> But guard our monarch's head;
> God save great George!

Great George himself had given his consent to the Acts for the union of Great Britain and Ireland, which were to take effect on January 1st, 1801; but, sadly perplexed by what he conceived to be the obligation of his coronation oath, was, by his refusal to agree to Pitt's plans for Catholic emancipation, about to drive the great minister to resignation, and himself into a fresh access of insanity. The country was at war with France. But Bonaparte, first consul of the Republic, "on entering into office," had addressed a letter to the King of Great Britain and Ireland, written on 5th Nivôse, which happened to be Christmas Day, 1799, and had asked:

"How can the two most enlightened nations of Europe, powerful and strong beyond what their safety and independence require, sacrifice to ideas of vain greatness the benefits of commerce, internal prosperity, and the happiness of families? How is it that they do not feel that peace is of the first necessity, as well as of the first glory?"

These admirable sentiments had little effect on the actual course of affairs, and to quote once more from the laureate' birthday ode:

> Still the expecting Muse in vain
> Reluctant Peace impatient woos,
> Still cruel War's destructive train
> O'er half mankind their vengeance loose;
> Still o'er the genial hours of Spring,
> Fell Discord waves her crimson wing.

In plain English, Bonaparte had crossed the Alps in May, and had won the battle of Marengo on June 14th. Colonel Arthur Wellesley, it may be observed, who was presently, as the great Duke of Wellington, to be the chief agent in putting a term to the ambitions of Napoleon, was at this time in India, and though he had won reputation as a commander and as an administrator in Mysore he was not considered, in spite of the influence of his brother, who was Governor-General, of sufficient experience and seniority to be entrusted with the command of a military force, which he had been charged to organise for an expedition to Egypt.

In politics Pitt and Fox were the great names, but the Tories seemed firmly established in the confidence of the Crown and of the nation, and Grey, who was to carry reform in 1832, was a Whig politician somewhat under a cloud owing to his supposed republican leanings.

Of the great literary renascence which was to give distinction to the first quarter of the coming century there were no signs, or none which either the critics or the public could discover. Burns indeed had lived and died, and in 1800 appeared the first volume of his collected works, edited with a biography by Dr. Currie of Liverpool. A second edition of *Lyrical Ballads* had been called for (the first had appeared in 1798); but Wordsworth had wrapped himself about with the silence which was to last for so many years, and Coleridge, writing leaders in the *Morning Post* for a living, was known chiefly as the translator of Schiller's *Wallenstein*. Walter Scott, a man of 29, had published nothing original; Byron was a boy of 12, not yet gone to Harrow; Shelley was a child of 8, and Keats of 5 years.

With regard to the sciences ancillary to medicine it may perhaps be said, without much fear of contradiction, that the movements which have had most influence on the development of medicine in the nineteenth century have been the establishment of chemistry on a sound basis of exact experiment, the cell theory propounded by Schwann, the great generalisation of Darwin, the discovery of the science of bacteriology, and the elaboration of the theory of optics. Now in 1800 Humphry Davy, to whom chemical science in this country in its early days owed perhaps more than to any one man, was in 1800 a young man of twenty-two engaged as Assistant at the Pneumatic Institution established by Dr. Beddoes in Bristol for the investigation of the medical properties of factitious airs and gases. Among other gases with which he was experimenting was nitrous oxide, but anæsthesia was yet far in the future, and Davy was not to commence his life-work as a chemist until the following year when he received an appointment at the Royal Institution. Thomas Young, "physician, physicist, and Egyptologist," was a young Cambridge don of seven and twenty, who in 1800 was engaged in attending the London hospitals before setting up in practice as a physician in Welbeck Street. The only distinct indication which he had given of his future achievements was in a paper communicated to the Royal Society in the previous year, in which he related the results of his first experiments on sound and light, which were, however, to prove the foundation of his theory of interference. Darwin was not born until 1809, Schwann until 1810, and Pasteur not until 1822.

The regulation of the practice of medicine and surgery, so far as it was controlled by the State at all, was committed to the care of the Colleges of Physicians and Surgeons in London, Edinburgh, and Dublin, to the Faculty of Physicians and Surgeons in Glasgow, and to the Corporations of Apothecaries in London and Dublin. Though the medical graduates of recognised universities had certain privileges, practically any person who could show any right to practise derived it from one or others of these colleges or corporations, although there can be no doubt that many practised without let or hindrance whose only qualification was their innate and not disinterested belief in their own fitness.

Owing partly to privileges possessed and enforced by the Colleges, but partly also to a real difference in education and attainments which have now been effaced, the line of demarcation between the physicians and general practitioners was very much more marked than at the present day, when the choice of the line of practice which a young man shall adopt depends far more upon the depth of his own or his father's pocket than upon any difference in ability or education.

What would now be called general practice was largely, if not entirely, in the hands of apothecaries, whose medical skill and general attainments apparently varied very much, though their social position was always respectable, and sometimes a good deal more. The right to prescribe had at the beginning of the century (1703) been won against the opposition of the College of Physicians; but at the end of the century the apothecaries were themselves engaged in repelling the attacks of the druggists, who not only dispensed the prescriptions of the physicians—a right claimed by the apothecaries as theirs alone—but also pretended to prescribe, and even to attend surgical cases, for instance, to reduce fractures. In fact, what would now be called the prescribing chemist had come into existence, with this difference, that he added to an ignorance of medicine and surgery an almost equal want of acquaintance with pharmacy.

The legal position of the apothecaries was, in fact, very ill-defined at the end of the eighteenth century, and so remained until the passage of the Apothecaries Act of 1815, which extended the jurisdiction of the Society of Apothecaries over the whole of England, and rendered any person practising as an apothecary without a certificate liable to a penalty of £20. The Surgeons' Company of London, which in 1797 had sold its property in the City and bought land in Lincoln's Inn Fields, had just been succeeded by the Royal College of Surgeons of England, which received its first charter from the Crown on March 22nd, 1800; but the Royal College of Physicians still claimed, though with diminishing confidence, to exercise some degree of jurisdiction over the surgeons as well as over the apothecaries practising in London and within a radius of seven miles. The College then had its local habitation in Warwick Lane in a building erected after the great fire of London from the designs of Sir Christopher Wren. It was taken into use in 1674, and Rowlandson's sketch, which is reproduced (p. 1837) to illustrate Dr. Blandford's article on City Life in 1800, no doubt shows the interior of the "great room or cænaculum...the...meeting room of the College, a noble apartment wainscoated in the most elegant manner with fine Spanish oak." A portion of the great room was standing as late as 1895, hidden behind Newgate prison and Cutlers' Hall in Warwick Lane. The room was approached across a courtyard, and the courtyard was entered from Warwick Lane under an archway over which Wren had put a dome which gave occasion for Sir Samuel Garth's rather obvious joke in the *Dispensary*:

> There stands a dome majestic to the sight,
> And sumptuous arches bear its oval height;
> A golden globe placed high with artful skill
> Seems to the distant sight a gilded pill.

The College continued to hold its meetings in this room until 1825, when it formally took possession of the house which it now occupies at the corner of Pall Mall East and Trafalgar Square.

Practitioners in England prescribed according to the *Pharmacopœia* of the Royal College of Physicians, commonly called the *London Pharmacopœia*, of which the last edition had appeared in 1788. Though it had undergone drastic revision in the middle of the century, it still contained many curious examples of polypharmacy. In Ireland the prescriber used either this volume or a *Pharmacopœia* which the King and Queen's College of Physicians had put out in a tentative way in 1794. In Scotland the *Edinburgh Pharmacopœia*, of which an edition had appeared in 1792, was used.

City Life in 1800.

By G. FIELDING BLANDFORD, M.A., M.D.Oxon, F.R.C.P.
Lecturer on Psychological Medicine, St. George's Hospital, London.

If we look back through the pages of history and compare the end with the beginning of successive centuries, we shall probably come to the conclusion that the changes which have taken place during the nineteenth century in the mode of life of the inhabitants of city and country are greater than those in any of the preceding. The end of the eighteenth century was a time of great gloom and depression, and it is doubtful if there was any real advance beyond that of the seventeenth. The contrast between the state of England under the vigorous rule of William of Orange and that under

the third George at the end of the eighteenth is painful to recall. Though the former monarch was nearing his end, yet, in the words of Burke, "the whole nation, split before into an hundred adverse factions, with a king at its head evidently declining to his tomb, the whole nation, lords, commons, and people proceeded as one body informed by one soul." Louis XIV had proclaimed the son of James II king of England. William recalled his ambassador from the French Court, declared war with France, and had the nation at his back.

War and Scarcity.

In 1800, also, England was at war with France, and had been since 1793, and so far as the army was concerned, everything had been disastrous, and there was great distress and dissatisfaction. The lower classes clamoured for peace—for peace and plenty—while a succession of bad harvests increased the price of bread and led to rioting and tumult. In 1795 there were meetings at Islington and elsewhere at which addresses to the nation and the King on the critical and calamitous state of affairs were voted, and when the King went in October of that year to open Parliament, he was hissed and hooted, and a bullet from an air gun perforated the glass panel of his coach, but without doing further mischief. Stones also were thrown, and after he had alighted at St. James's the coach was smashed. In 1797 the Bank of England stopped cash payments and paid everything in notes, which were issued for small as well as for large sums, and were often compared with the French *assignats*. The 3 per Cents. fell to 48. In 1799 there was such trouble and distress among the poor that a subscription had to be opened to assist them, as had been already done in 1795. In February, 1800, in order to prevent a useless expenditure of wheaten flour by the consumption of new bread, a Bill was passed prohibiting any baker in London or Westminster, or within ten miles of the Royal Exchange, from selling bread until it had been baked twenty-four hours under a penalty of £5 for every loaf sold. Later in the same year there were riots in the city, and mobs assembled at the Corn Market and broke open shops of bakers and corndealers. There were at this time no police, and such gatherings had to be dispersed by soldiery, mostly volunteers. The century closed by a proclamation issued on December 3rd exhorting all persons who have the means of procuring food other than corn to use the strictest economy in the use of every kind of grain by abstaining from pastry, and reducing the consumption of bread in their respective families.

Thus the century died. Prices at the end were terribly high, and wheat was £5 13s. per quarter, the 4 lb. quartern loaf costing 1s. 10d. In 1798 a quarter of wheat cost only £2 9s. 8d., coals, meat, butter, candles, rates and taxes had risen in like proportion. The farmers were having a profitable time, and loud was the outcry that they held back their corn to keep up the price. In January of the new year the sale of fine wheaten bread was forbidden, and none allowed to be sold but that which contained the whole meal with the bran. All this added to the clamour for peace, so, after Bonaparte's serious reverses in Egypt, negotiations began, and before the end of 1801 the preliminaries were signed, and illuminations and rejoicing celebrated the event. Wheat fell and Consols went to up 65. But Bonaparte's peace was a mere device, and in 1803 war was again declared.

The population which had to be fed at the beginning of this century was a small one compared with that of the present day. The total population of England and Wales in 1801 was 8,892,536, and of this number 4,721,252 lived in rural districts—that is, rather more than half. In 1891 the total population of England and Wales was 29,002,525, and of this number 5,534,000 lived in rural districts—that is, not quite one-fifth. Instead of being paramount as in 1801, rural interests in 1891 were those of less than one-fifth of the whole people.

London in 1800.

In order to make any fair comparison between life in the towns at the end of the last century and at the present day it will be best to try to draw a picture of London in 1800, for the population of no other town at that day would bring it fairly into the same category with the great centres of today. London in 1801 had 922,000 inhabitants; Manchester, the next most populous town, only 121,000.

Though densely crowded in certain parts, London was a much smaller place than it is now. What its exact size was we can learn very accurately from an excellent map prepared in 1799 by Horwood for the Phœnix Fire Office. In this, which is on a large scale, 26 inches to the mile, not only every street but every house with its number in the street is delineated, and we have a complete picture of the town and its suburbs, with all the fields and market gardens then existing.

If a citizen started from the Bank and walked north by Finsbury he would find the streets completed as far as Old Street, but thence to the Angel at Islington there were only a few houses. If at Old Street he turned west he would reach Clerkenwell, then thickly covered with houses which extended a short distance north of Clerkenwell Green, whence a stretch of fields led past the New River Head to Islington. Continuing west he would find that the House of Correction and Foundling Hospital were the boundaries of the town, and from the latter the foundlings looked across fields to Somers Town and Highgate. Russell Square and all north of it were fields, but Tottenham Court Road and the adjoining streets were finished as far as the New Road, now called Euston. In this New Road there were no houses with the exception of a few near Baker Street. Mr. Lord's Cricket Ground was where Dorset Square now is, and to the west was a nursery and Lisson Green. A row of houses fringed one side of the Edgware Road, but Upper Berkeley Street and Gloucester Place were the limits of buildings in this neighbourhood. The Grosvenor estate round Grosvenor Square was by this time covered with houses, as was all the land between it and Piccadilly. There were a few houses at the top of Grosvenor Place as far as Chapel Street, but from thence one could walk across the Five Fields to Sloane Square. Kensington and Chelsea were separate and distinct places, the Brompton Road and Sloane Street were bordered by houses, but only a small portion of Chelsea was built upon round the hospital and church. Chelsea Common with a cricket ground and various nurseries occupied the remainder. From Chelsea Hospital or Ranelagh, if our wayfarer looked east, no buildings interrupted his view of the towers of Westminster Abbey, but he would see a few houses in Rochester Row and Horseferry Road between him and the ancient city of Westminster with its many streets; all between was Tothill Fields, where long since the beginning of the century snipe have been shot, a favourite haunt of cockney sportsmen, such as Seymour loved to delineate.

On the other side of the river lay Battersea, Kennington, and Lambeth, with many a field and marsh between them. Further east was the closely built and thickly inhabited borough of Southwark and the old parish of Bermondsey, whence some houses bordering the river led to Rotherhithe;

all south of these parishes was fields. Crossing the river again he would find a fringe of houses on its bank as far as Limehouse, after which came the Poplar marshes. Stepney was a village separated by fields from Mile End, and from Stepney to St. George's Church were fields. There were some streets east of Shoreditch, but Bethnal Green and Hackney were quite in the country.

Dress.

What manner of men and women were they who inhabited this London and walked in its streets? We gain much information on their dress and appearance from the caricatures of the time, and as we learn the fashions in vogue from the drawings in *Punch* by Leech, Keene, or Du Maurier, so we may study the manners and costumes of 1800 in those of Gillray and Rowlandson. The latter illustrated books as well, and from his figures it is easy to see what our forefathers and foremothers wore. The French rage for the so-called classical dress had extended to England in spite of the war. "No one," we are told, "can doubt the beauty of this style of dress, but it was totally unfitted for outdoor use and even for evening dress." It clung close to the figure with very high waist, and was only suited to the young and slight. It does not appear to have been carried to such extremes here as in France, where the dresses were very *décolletées* and at the same time very short. A lady having asked Talleyrand if he admired her gown, "*Oui, Madame*," he replied," "*C'est magnifique, mais elle commence trop tard et elle finit trop tôt.*" The English ladies wore their dresses low and arms bare out-of-doors, and the dresses were of such thin materials that one wonders how in our climate they ever kept themselves warm. Petticoats they had none or next to none, for there was no room, and drawers had not come into fashion, and did not till the third or fourth decade of the century. They began with children's pantalettes, but older people did not wear them for warmth till much later, there being a strong prejudice against donning so masculine a garment. The stockings and shoes were as thin as the dresses. The bonnets just at this time were of the "poke" order, but there were many varieties, and the fashion changed continually. The men were nearly as eccentric in their dress as the women, and they too affected tight clothes. There were many *macaronis*, dandies, or bucks, who carried fashions to an extreme, wore two watches in two fobs, padded their shoulders, and had their collars as high as their hats. No one wore trousers; these came much later, and were violently resisted. Even so late as in 1812, undergraduates at Trinity and St. John's, Cambridge, were forbidden to come into hall so clad. In 1800 all had knee breeches and stockings, top boots, or gaiters, except a few who wore tight-fitting pantaloons and Hessian boots. In the evening or when full dressed, all donned breeches and silk stockings. Perukes, periwigs, or as the word was shortened, wigs, were rapidly going out, but the professions—divinity, law, and physic—still adhered to them, as have the lawyers to the present day. In a picture of a *comitia* at the old College of Physicians in Warwick Lane (p. 1837), Rowlandson has represented the whole of the Fellows as wearing white, that is powdered, wigs. Some of the bishops retained the wig to our own day. Hair powder was not so much the fashion since Mr. Pitt put a tax on it in 1795, a tax which was only repealed in 1869, but which at first brought in £20,000 a year. Men did not now carry swords, except when full dressed, neither did they carry umbrellas; for although Jonas Hanway was said to have invented them so far back as 1755, they were in 1800 considered feminine and Frenchified, and were only used by ladies. Hats varied much; the three-cornered hat was dying out, and the high-crowned hat was beginning. This was generally made of beaver, and also had to pay a tax.

The Streets.

When the citizens of London walked abroad the streets did not offer many attractions; the shop windows were high, with small panes of glass, and no great show was made in them. There was pavement in the principal streets, but in all others "kidney" stones formed the *trottoir*, and after rain the water flooded the roadway for want of channels and sewers to carry it off. The dismal processions to Tyburn were abolished, but a man in the pillory at Oxford Street or Charing Cross was occasionally to be seen. Cabs and omnibuses there were none. Those who wanted to ride had to take a hackney coach, the fare of which for one mile and a quarter was a shilling, and sixpence for every half mile further. Then there were also hackney chairs, while those who were near the river could go by water with either oars or sculls at very moderate rates—for example, from London Bridge to Chelsea, Battersea, or Wandsworth the fare with oars, that is two watermen, was two shillings, with sculls one shilling. To reach the country or suburbs there were stage coaches and stage waggons, the latter a cheap but slow conveyance that we read about in Smollett and elsewhere.

Public Amusements.

Places of amusement were not numerous. There was the British Museum in old Montague House, but access to it was not easy, for visitors had to leave their names on one day and call for tickets on the next, the tickets specifying the day and hour of their visit. There were the animals at Exeter Change, and some more at the Tower; and in 1802 Madame Tussaud brought over her wax figures from France. Before that time Mrs. Salmon exhibited waxworks in Fleet Street, and there were always those in Westminster Abbey. There was at this date no National Gallery, but the Royal Academy existed, and held an exhibition once a year. The multitude cared little for pictures. What it loved was tea-gardens, and of these there was an abundant supply in all parts of London. White Conduit House, Bagnigge Wells, and Islington Spa were in the north. Kensington Tea Gardens, Marlborough Tea Gardens, and Union Tea Gardens were in the west; the Yorkshire Stingo, and Kilburn Wells were near the Edgware Road: Chalk Farm, Canonbury House, Highbury Barn, and Hornsey Wood House were all in localities known in modern times, and a dozen or more might be enumerated did space permit. Open-air amusements were much in fashion, especially at night, and Vauxhall and Ranelagh were long frequented by the rank and fashion of the town. Outdoor singing and dancing took place at the smaller as well as at these fashionable places of resort.

Eating and Drinking.

It was an age of heavy eating and drinking, of dinners when the table "groaned" under a weight of dishes containing food enough for four times the number of guests. This fashion had lasted many years before the end of the century and did not cease till long after the commencement of the present—till, in fact, the dinners *à la Russe* supplanted it. Mrs. Lybbe Powys in 1781 mentions having been at a dinner at Norwich at which the guests were seventeen and the first course consisted of eighteen dishes, including the two soups. The big dishes would be placed at the ends of the table, and along the sides would be an array of others, all of which had to be carved on the table by guests of more or less skill, then removed and others put in their places; in the middle were wine coolers to hold the

A Comitia at the Old College of Physicians in Warwick Lane. (From a drawing by Rowlandson.)

champagne, while sherry or madeira decanters were scattered up and down. Even so late as 1835 Mr. Walker in the *Original* says: "As tables are now arranged, one is never at peace from an arm continually taking off or setting on a side-dish or reaching over to a wine-cooler in the centre. Then comes the more laborious changing of courses, with the leanings right and left, to admit a host of dishes that are set on only to be taken off again, after being declined in succession by each of the guests, to whom they are handed round." These huge displays of dishes necessitated large and handsome joints, poultry, fish, and game at a ruinous expense, and must have been a source of great discomfort to the guests.

The drinking was no less heavy than the eating. Teetotal or temperance societies were things of which one heard nothing at the end of the last century. Teetotallers of to-day would say without much exaggeration that every man drank to excess 100 years ago. Getting drunk was no disgrace, and was almost the rule in evening entertainments. It is recorded to the credit of Pitt, then Prime Minister, that he never was seen drunk in the House of Commons except on one occasion. Yet he drank port wine immoderately, suffered from gout, and died at 47. With the eating then prevalent, and the drinking of port wine, gout attacked numbers, and in the caricatures a man with his foot swathed in flannel and bandages is a constant object. At dinner parties the drinking was for the most part during the dessert, but at the meal it was the fashion for the guests to take wine with the host and with each other, and a good deal was consumed in this way. This fashion prevailed throughout the first half of this century.

Here are some of the prices paid for wine according to a wine merchant's list of this period. For superior old port, 38s. per dozen; prime old sherry, 42s.; prime old madeira, 63s.; bucellas, 40s.; mountain, lisbon, and calcavella, 38s.; superior claret, 70s., claret being a French wine was expensive; cognac brandy was 20s. per gallon, old Jamaica rum 15s., and Geneva 10s.; champagne is not mentioned in the list. These were the days of three-bottle men, who were not uncommon. One bottle or two bottles were hardly worth recording. Yet we read in the *Morning Post* of July, 1800, that "at a village in Cheshire three clergymen after dinner ate fourteen quarts of nuts, and during their sitting drank six bottles of port wine and no other liquor." Beer, however, was the national beverage, and was brewed out of malt and hops, and not out of glucose. Beer was drunk at all, or nearly all dinners in the last course, and in the annals of a dinner club which still exists, strong beer and spruce beer figure in the bills at the end of the eighteenth century.

If our ancestors drank more they certainly smoked less than we do. Cigars—segars, as they were often written—

though not unknown at this time, were by no means common, nor did they come into general use till after the battle of Waterloo. Smoking was done by means of the long churchwarden pipe, but did not take place at every dinner or where there were ladies. People took their tobacco in the form of snuff, and this was universal; both ladies and gentlemen carried a snuffbox, and George III's Queen Charlotte was usually depicted with one in her hand.

HOUSES AND THEIR WATER SUPPLY.

What of the houses in which the inhabitants of London in 1800 lived and died? We know something of them, for a large proportion of the City and West End which was then built is standing and inhabited now. The great fire destroyed a large area in the City, and the rebuilding was an improvement in many respects. In the West good substantial houses had been built by the brothers Adams and others, which are still in use and in good repair. But sanitary methods and appliances were in their infancy. Probably at this date there was not such a thing as a bath room in the whole of London, and, as a witness remarked before the Health Commission towards the middle of the nineteenth century, the only two occasions on which one of the labouring classes was washed all over were after he was born and after he had died. Appliances for washing did not go beyond the footbath, and folks used but little water, for the good reason that they had not much to use. The well-to-do by this time had water brought into their houses from waterworks in most quarters of the town, the Chelsea waterworks supplying the West, the New River and the works at London Bridge serving the City and northern parts. But many of the West End houses had their own well and pump, and have still, though we will hope it is not used. Even in 1800 the contamination through the London gravels must have been very serious. In Lambert's *History of London* (1806) we read that "No city in the world is better supplied with water than London, every house in which may receive a regular supply of this necessary article three times a week by paying a moderate annual sum to one of the water companies." Drinking water was carried about in barrels from favourite springs at Hampstead and elsewhere to those who could afford to pay for it.

The old rivulets which in ancient days supplied Londoners with water had long before 1800 passed first into the quality of dirty ditches, and thence into sewers. Such was the Fleet, the River of Wells as it was called, from the number of wells which poured their contents into its stream. From being the Fleet River it became the Fleet Ditch, and was converted into a sewer, but not completely covered in till about 1841. Another was the Tyburn, which once supplied the City with water and shared the same fate. And a third was the Westbourne, which, flowing down the Serpentine, became the Ranelagh sewer, and runs in an iron pipe through Sloane Square Station unto this day. There were other sewers by 1800 in the different parts of the town, and Lambert speaks of "arched vaults called sewers communicating with each house by smaller ones." It is very doubtful, however, whether this was generally the case. The system in 1800 was one of cesspools, which at first had no communication with the street sewers, but were emptied by "night men," who worked by night as the dustmen by day. About 1778 Joseph Bramah, the lockman, patented an improved watercloset, which was adopted and continued till quite modern times, but it came into use very slowly, and it is not likely that there was a high service of water at the end of the last century, at any rate in the west of London. If a watercloset was joined to a cesspool, and there was no communication with the sewer, the overflow soaked into the surrounding soil. There were no pipe drains; at this date all were of the old brick-barrel kind.

MUNICIPAL POLICE.

The streets were lighted in 1800 by oil lamps, and a few private houses had the same sort of lamps at their front doors. These lamps had to be filled with oil and trimmed, and various caricatures portray this process to the detriment of the passers-by. Indoors candles were almost the sole illuminant, wax candles or tallow candles, which required frequent snuffing. The writer remembers a church near the Royal Exchange, where at evening service an old man went round with a pair of steps and large snuffers, and snuffed the candles at intervals. Gas was not introduced till later. Westminster Bridge was lighted with gas in 1813, and the streets generally in 1814. Their insecurity in 1800 was increased by there being no police. By day they were not patrolled at all, and at night they were entrusted to the care of a small number of ancient watchmen, veritable Dogberrys, who armed with a staff, a rattle and a lantern, called the hours, and then retired to a sentry box till the next call was due. There were a few Bow Street runners and constables at the police-courts, chiefly employed in thief-taking, but the new police of Sir Robert Peel were not introduced till 1829. In 1800 severe punishments were thought the best preventive of crime, and there were no fewer than 160 offences for which capital punishment was the penalty. Among these were such as "stealing a cotton counterpane," "stealing a pair of stockings," "six silver spoons." These sentences were passed at the Old Bailey in September, 1801.

CHURCHYARDS AND BURIAL GROUNDS.

When the end came and the Londoner lay dead, where was he to be buried? First he had to be wrapped in woollen. This had been the law for many years, a law which was not repealed till 1815, and was supposed to benefit our woollen manufactures. Then he was "inspected" by inspectors appointed for the purpose. He was buried in London, for not till long after were there any extramural cemeteries. In 1800 every church had a churchyard, with few exceptions, or the parish had graveyards elsewhere. In the parish of St. George Hanover Square the graveyard was in Mount Street, and when this was filled another was opened in the Bayswater Road, and besides the graveyards there were vaults under many of the churches. There were no fewer than seventy-two parish graveyards outside the City in addition to the large number attached to the city churches, and there were also by this time some private burial-grounds started as speculations, owing to the overcrowding of the parish grounds. They were none of them large, and soon became filled, for their charges were cheap. The overcrowding and the practices adopted in them to make room for more were so disgusting that they contributed not a little to the passing of the Act under which the metropolitan burial-grounds were closed in 1852.

After death there was yet another terror—the resurrection man. At this time the only subjects for dissection were the bodies of those executed for murder, and as the teaching of anatomy was now zealously practised in many schools, subjects were an absolute necessity, and were not to be obtained in any other way. This state of things went on for many years, for it was not till 1832 that the Anatomy Act was passed. The numerous burial-grounds in London gave great opportunities to the body snatchers.

Such was life in 1800; what it is in 1900 we know. What will it be like in 2000?

Anatomical Teaching in 1800.

By ALEXANDER MACALISTER, M.D., LL.D., F.R.S.,
Professor of Anatomy, University of Cambridge.

Of the changes which have taken place in medical education in the course of the nineteenth century, few are greater than those in the method and extent of anatomical teaching. This was the only scientific branch of the curriculum which, at the beginning of this period, was studied by practical work, but the nature and kind of the laboratory instruction then given differed widely from the dissecting-room teaching of the present day.

The "anatomy" taught in 1800 was certainly wide and comprehensive. I have the good fortune to possess several students' notebooks on the subject, containing the abstracts of the anatomical lectures in various schools about the beginning of the century. From these and the textbooks in use one learns that it included not only what was known of the structure of the body, but also the current theories of the functions of organs, as well as their relations to injuries and disease. Those who taught were practising surgeons or physicians, and their primary aim was to make emphatic the applications of anatomy to surgery or medicine; indeed, more than half of the lectures was taken up with morbid anatomy or the recital of cases.

A Last Century Dissecting Room. The figure standing up above the rest is William Hunter; his brother John is on his right-hand side, and Matthew Baillie is the next figure to William Hunter on the left; Cruikshank is seated at the extreme left of the picture; and Hewson is working on the eye of the subject on the middle table. (From a drawing by Rowlandson.)

Minute Anatomy.

Of the minute anatomy of tissues little was known beyond that which could be seen with the aid of a simple lens, for the compound microscopes of the period distorted as much as they magnified. The student had generally to be content with the word of his teacher in this and several other departments, and was seldom practically instructed in the art of verifying by original observations the descriptions given. John Bell, one of the best teachers of his time, scoffs at the "noisy mistake" of the Abbé Torré in supposing that red blood corpuscles are other than spherical, and says that the deception arises from some strange refraction either an effect of lenses or in the nature of these globules. According to him, the Abbé's spherical lenses magnified too highly.

Textbooks of the Day.

Dissection was hampered by the scarcity of bodies which there was no legitimate method of procuring, and was limited by the difficulties attendant on their preservation. In consequence it was usually hastily done, and restricted to the general topography of the viscera and to the cleaning of muscles and vessels. The latter could be injected easily, and the injected preparations could be rendered permanent by steeping in turpentine, drying, and varnishing. Preparations of this kind were kept in most medical schools, and hence a fairly good knowledge of the courses and branchings of the arteries was easily acquired, and constituted a large part of the anatomy which a student had to learn. Veins and lymphatics were little noticed, except such of the former as were superficial, and the peripheral nervous system occupied but a small part of the course. In the large *Edinburgh Anatomy* published in 1784, out of 1,410 pages of text the whole peripheral nervous system occupies 20, and, though written by Monro, is of the most meagre description. For example, in speaking of the cutaneous nerves of the hand, he says: "In

describing the posterior branches of the ulnar and muscular nerves, I did not mention the particular fingers to the convex part of which they are distributed. My reason for this omission is the uncertainty of their distribution; for though sometimes these posterior branches go to the same fingers to the concave part of which the anterior branches of the ulnar and radial are sent, yet frequently they are distributed otherwise" (iii, 325).

In the account of the brain in the textbooks of that day there is no description of structure, and little more than the list of surface markings on the exterior or within the ventricle.

The method of teaching was systematic, not topographical. Textbooks were all constructed on this plan, and had not (as the systematic textbooks of the present day have) directions for the dissection of each part. The separate guides to topographical anatomy now so universal, did not appear in Britain until about the end of the first quarter of the century. Scratchley's miserable *London Dissector* came first; then the anonymous first edition of the *Dublin Dissector*, written by Harrison; and later, the *Edinburgh Dissector*. Particulars concerning anatomical teaching at this period are given in the *Memoirs of James Macartney*, and the life of J. F. South.

As a type of the textbooks then in use, one of the best and most characteristic is that of John Bell, of Edinburgh, of which the second edition was published in 1797. This only included bones, joints, muscles, and arteries. In the third edition, published in 1811, Sir Charles Bell added a description of the nerves and viscera. The second edition consists of two large octavo volumes of 955 pages. It is written in a lively though somewhat verbose style. Were the material it contains sifted and all that is now regarded as descriptive anatomy selected and put together, this bulk would be diminished to less than one-third; and, were the facts in those selected portions expressed in the terse form which it has become necessary to use nowadays in anatomical manuals, they might be fully expressed in half that space.

In this farrago of archaic physiology, of morbid anatomy, of comparative anatomy, and of surgery through which the slender stream of descriptive anatomy meanders we miss two things: First, the definiteness and precision which characterise modern anatomical descriptions; and, secondly, instruction as to method whereby the statements may be verified. There is not from first to last a single direction as to the method of dissection. Indeed, he says that many things are better to be "read in the closet than taught in any public course."

In his preface of twelve pages he deprecates technicalities, "the pride of anatomists and the disgrace of their science." But his abstention from the use of specific names makes his descriptions exceedingly vague.

THE BONES.

The first book is occupied with the account of the bones, and begins by thirty-five pages of generalities concerning the growth of bones and the formation of callus in fractures. There is no reference to Haversian canals, although Gagliardi's pegs are mentioned. This is followed by detailed accounts of the several bones, beginning with those of the head, which occupy seventy pages, of which six are occupied with consideration of fractured skull, the relation of sutures to drainage, etc. His style in describing the bones may be exemplified by his account of the inferior turbinal bones, which are "very spongy, much resembling puff paste, having exactly such holes, cavities, and network as we see in raised paste. They lie rolled up in the lower part of the nose, are easily seen either in the entire subject or in the naked skull. Their point forms that projection which is touched by the finger in picking the nose, and from that indecent practice very often serious consequences arise." Then follows a page on polypi and other conditions, in the course of which the position of the bone is given thus: "The curling plate hangs down into the cavity of the nostril with its arched side towards the nose." "It has no cells connected with it," and it "covers the end of the lachrymal duct." "In the bare dissected skull we find a neat small hook upon the spongy bone by which it is hung upon the edge of the antrum maxillare, for this lower spongy bone is laid upon the side of the antrum, so as to help the palate bone in closing or covering that cavity from within."

The other bones occupy 20 pages and the principal characteristic of the accounts of these is the vagueness of description, which gives no help in the attempt to visualise the part. There are also positive inaccuracies, for example, he says that the neck "according as it is long or short sometimes has eight pieces, sometimes only six": that the rib "being fixed to the body of one vertebra and to the transverse process of the vertebra below the motions of the vertebræ are much curbed." In the account of the pelvis as much space is taken up by discussion as to the occurrence of loosening of the pelvic joints during labour as is occupied by the actual description the pelvic bones themselves.

The muscular attachments are seldom mentioned in the description of the limb bones; indeed, not one muscle is mentioned as being attached to the shaft of the femur. Of the metacarpus he says, "Nothing of importance can be said concerning the individual bones. To speak of them individually is a mere waste of time." How a present-day student would love an examiner who thought so little of such details as Bell does!

THE MUSCLES.

In the 197 pages describing the muscles of the body the attachments are given shortly and in general terms. For the most part he follows Winslow, Cowper, Douglas and Albinus in his accounts of them. Nearly as much space is taken up in detailing their uses as in describing their attachments, and in no case is nervous or vascular supply mentioned. The account of the muscular system concludes with 17 pages on muscular contraction, containing neither an account of muscular structure nor of any of the then known experiments on muscular action. The general tone is a deprecation of the attempt to import physical or mechanical considerations into the study of the *vis insita*, which he regards as an inherent and original attribute of muscle. The descriptions of tendons, bursæ and sheaths are general, and there is no attempt at topographical description, although Monro's treatise had been published nine years before. The younger Monro, although in his *Elements of Anatomy* he only gives a very short account and classification of bursæ takes occasion to introduce Sömmerring's eulogy on his father's work.

JOINTS.

The joints, which fill 53 pages, are meagrely given, but the accounts, though falling far short of the detail of present-day work or of the precision of the newer animal mechanics, yet are on the whole of more value than the accounts of the bones.

CIRCULATORY SYSTEM.

In the second volume the account of the heart is good, but takes careful reading to understand, while it is spun out to 250 pages by long digressions on the circulation, on respiration, on exploded views of the fœtal circulation, so that the

descriptive part is masked, and the student's mind left in a maze with the discussion of conflicting hypotheses. The latter half of the volume, on the anatomy of the arteries, is the best bit of real descriptive work in the book, but according to modern notions fails from the want of detailed relations. Many actual mistakes occur. He makes the superior laryngeal artery enter between the cricoid and thyroid cartilages, and brings the greater sciatic nerve over the pyriformis. Here the second edition ends, but to the third the author's brother Charles has added chapters on the remaining parts of the anatomy. These consist of a very brief description of the brain and a still more insufficient account of the peripheral nerves, which in this edition are placed at the end of the second volume.

Special Senses.

In the third volume, also by Charles Bell, the organs of sense are first treated, beginning with a psychological disquisition on sense perception, and a sketch of the principles of optics, which occupy 25 pages. Then follow about 100 pages on the anatomy of the eye, of which more than one-third is taken up with digressions on the seat of vision, squinting, nyctalopia, etc. The anatomy of the ear is treated in much the same way, but here the description is padded out with accounts of the ear in the lobster and other animals, with details concerning diseases of the tympanum, and on the sense of hearing.

Abdominal Viscera.

After the senses come the abdominal viscera, treated more physiologically than anatomically, and he sarcastically criticises those who attempt to reduce physiology to a physical process. "Let us be satisfied with knowing a little. The life residing in the gland is an agent controlling the affinities."

The illustrations absent in the first volume, few in the second, are more numerous in the later third, but are of very little use in rendering the text intelligible. The student whose knowledge was derived from such a textbook might be amused with the destruction of effete theories, but would have, except in the article of arterial branchings, a poor acquaintance with human structure.

The century has taught us that anatomy is nothing if not definite; that anatomical illustrations for the use of students must be diagrammatised; and that the real nexus whereby the discrete facts may be best strung together is morphological relationship. It has been said that human anatomy is a worked-out field; the comparison of old textbooks with those of the present day is the best refutation of this charge, which is based on ignorance, and it is by no means improbable that those who see the end of another century will be able to record advances both in knowledge and method even greater than those that have taken place in the last hundred years.

Physiology in 1800.

By HENRY POWER, M.B., F.R.C.S.,

Professor of Physiology Royal Veterinary College; Consulting Ophthalmic Surgeon St. Bartholomew's Hospital.

Physiology as a separate study can hardly be said to have existed in this country at the commencement of the present century. In books and in lectures alike it was united with, and considered a part either of medicine under the general term "Institutes of Medicine," or of anatomy. In the great schools of medicine of the Metropolis they were not divided until the first thirty years had passed away. The University of London set the example, which was soon followed at Guy's Hospital. In an advertisement of 1833 the statement is made that lectures at this hospital were the only special lectures on physiology delivered in London, excepting the course at the London University, then under the charge of Dr. Sharpey. At Guy's the curious practice existed of confiding the teaching of physiology to the lecturer on midwifery, and Dr. Haighton and Dr. Blundell successively held the two offices. In 1846 anatomy and physiology having been in the interval taught simultaneously by Bransby Cooper, the two subjects were once more separated, and the lectureship on physiology was entrusted to Dr. (afterwards Sir William) Gull. Soon after, certain evenings in the week were devoted to instruction in microscopic work, and Mr. Birkett, who still survives to witness the immense development of the subject he taught in its infancy, was appointed the teacher. Histology was associated with physiology when Dr. Pavy succeeded to the chair in 1857, and classes in practical physiology, at which the use of the microscope was taught, were first instituted at this school in 1871. The process of the separation of physiology from anatomy and the introduction of histology followed a similar course in other schools.

The extraordinarily rapid development of physiology is partly owing to the great advances that have been made in chemistry and physics, the sciences on which it rests, and partly to the progress effected in the means of observation. The balance and the methods of chemistry, the microscope and the methods of the histologist, have introduced a degree of precision into modern research unattainable by the older inquirers, who trusted to the unaided senses and have enabled observations to be made revealing the internal processes of the economy almost as astonishing as those which result from the application of the Roentgen rays in displaying the form and position of the bones of the living man.

The tendency of modern research is to show that all those acts and phenomena which were formerly regarded as the results of the operation of a special force, the vital force, are to be explained by the ordinary laws of physics and chemistry. There are many processes that are still enigmatical. We do not know the exact chemical changes that precede the evolution of hydrochloric acid in the gastric juice, nor the mode in which impulses are propagated along nerves, but it is presumed that in both instances intelligible, though perhaps not thoroughly comprehended, molecular changes take place, and that they are certainly not due to the supposititious "anima," or vital spark, which the older writers so readily accepted.

The physiological works published in the eighteenth century were few and unimportant, and were chiefly written in Latin or German. The monumental treatise of Baron Haller, the *Elementa Physiologiæ Corporis Humani*, appeared in eight volumes between the years 1757 and 1766. He had already, as early as 1747, sent forth a small book, entitled *Primæ Lineæ Physiologiæ*, which was a precursor as well as a condensation of his larger work, and translations were immediately made into French and English. In 1786 a translation was published under the auspices of Dr. Cullen, the well-known Professor of Medicine in Edinburgh. This book, with notes by Wrisberg, constituted almost the only physiological work in the hands of the student in this country, whilst the original was used in most of the foreign universities. It represents the high-water mark of physiological knowledge at the close of the last century, and in considering the progress of physiology during the present century it may advantageously be taken as standpoint.

BLOOD.

Taking the subject of the blood and circulation, it may be noted that the physical characters of the blood, its coagulability, and the morphological elements it contains, were fairly well known, owing to the observations of Malpighi, Leeuwenhoek, and Jurin abroad, and those of Hewson and Hunter in this country. It is remarkable that no separate section is devoted in Haller's *Primæ Lineæ* to an account of the blood, the little that is said of it being given under the head of "Secretion." The corpuscles were held to be globular, but the estimates of their size were remarkably correct considering the instruments used. Blumenbach gave their diameter as $\frac{1}{3500}$ inch, and Sprengel $\frac{1}{3000}$ to $\frac{1}{3200}$. Haller's estimate was too low—$\frac{1}{2000}$—but the method he adopted was ingenious, for he compared their size with that of the scales on the wings of a butterfly, which, being arranged in rows, permitted the number in an easily measurable space to be counted. The composition of the blood, the existence of hæmoglobin with its special affinity for oxygen, the origin of the blood corpuscles, their numbers, the mobility and diapedesis of the white corpuscles, the absorption bands the blood presents under spectrum analysis were all unknown, and the cause of the coagulation of the blood, which, however, is even now a subject of discussion, is wholly ignored.

CIRCULATION.

The fundamental facts in regard to the action of the heart and the circulation of the blood were established by Harvey in the seventeenth century, and the principal addition made to his conclusions in the eighteenth were founded on the classical and extremely ingenious experiments of Hales on the pressure of the blood in the vessels. The importance of a correct appreciation of the causes of the sounds of the heart and their relation to its movements in medicine led to many researches being undertaken both in this country and abroad at the commencement of the present century. It was not surprising in view of the many difficulties attending the experiments that the conclusions arrived at were in some instances conflicting, and the order of the movements of the heart and of its divisions could scarcely be regarded as settled until the introduction of the graphic method in the hands of Volckmann, Vierordt, Ludwig, and Marey. The employment of the mercurial manometer by Poiseville in place of the long and cumbrous glass tube of Hales enabled the blood pressure in each vessel and in different animals to be easily ascertained, and the cleverly-devised double tubular sound ending in an elastic bag devised by Chauveau, and introduced through the vena cava and auricle into the right ventricle, permitted the pressure of the blood even in those not easily accessible cavities to be registered with comparative facility. The remarkable observation of the brothers Weber in 1845 on the restraining influence of the vagi on the heart opened up a new chapter in physiology, and the phenomena of inhibition, as the effect is named, have been shown to constitute an important function of the nervous system in many other instances. It led to careful examination of the influence of other nerves on the action of the heart, and the origin and course of the accelerating and inhibitory cardiac nerves are now well known. The discovery by Cyon of the depressor nerve, which influences the action of the heart by acting as a vaso-dilator of the vessels of the abdominal viscera, was also of great value. The sphygmograph, by which the number and form of the pulse waves can be accurately shown, though valuable in some instances, presents difficulties in its clinical application that has prevented its general introduction into medical practice. The structure of the heart and vessels was first thoroughly elucidated by the careful microscopic observations of Kölliker, and various instruments have been devised by Volckmann, Ludwig, and others to determine the rapidity of the pulse wave and of the flow of the blood.

SECRETION.

The knowledge of protoplasm and of its immense importance being unknown, perhaps the chapter in physiology in which the teaching was most foggy was that dealing with the secretions of the various glands. Withdrawn from observation by their concealed position, the subjects of innumerable fanciful and often absurd speculations, misunderstood by reason of the imperfect chemical knowledge of the day, such glands as the liver and pancreas with their secretions were riddles hard to read by Haller and his contemporaries. Their conclusions were vitiated by two errors. First, that the secretions existed preformed in the blood, and, secondly, that the blood vessels and the ducts of the glands were in their finest ramifications continuous with each other. Thus Haller observes that "there are many arguments to persuade us that the liver is a mere vascular fabric, whence the bile distils immediately from the extremities of the porta into the pori biliarii or roots of the biliary ducts without passing any cells or follicles by the way."

Elsewhere, after pointing out that the blood contained coagulating serum, water, viscid mucus, and oil, he maintains that the blood vessels entering the glands represent strainers the length, size, and form of which determine both the nature and the escape of the particular constituent of each secretion. The differences in the quality of the secretion depended, in his view, upon the position its particles occupied in the blood stream. Fat and marrow were believed to be deposited without the intervention of glands from the small mouths of the minute arteries into the cellular substance; the secretion of the various forms of sebaceous glands, and of milk, was due to the separation of the oily portions of the blood, and the mucus of the surface of the intestine and genito-urinary tract to the separation of the mucus previously existing in the free state in the blood.

The secretions of the thinner juices were considered to be made not from sanguineous but from smaller pellucid arteries arising from the former, to the secerning mouths of which not only no red blood, but no serum, fat, or other gross material could have admittance. It is in this way "that the more thin and pure humours"—those of the eye, for example—"must necessarily be separated." Nor was less importance attached to the angles at which the smaller vessels were given off from the trunks; different secretions being formed according to whether the mode of ramification of the arteries was, as in the spleen wisp-like, or as in the intestines pencil-like, or like serpents as in the kidneys or in the form of stellæ as in the liver or in a "radiated circle" as in the vivea, or like a lock of hair curled up into the form of a button as in the testis.

Haller well knew how to cover ignorance by high-sounding phrases, and the following paragraph may be quoted as a good example of darkening counsel by words. Speaking of the bile he says: "It takes in the saponaceous water of the stomach by the absorbing veins together with the subfetid alkalescent vapours of the abdomen, which transpire through the whole surface of the intestines, stomach, omentum, liver, spleen, and mesentery, which are absorbed again by the veins as we know by incontestable experiments of anatomy; and, finally, the alkalescent semi-putrid acrimonious humidity from the fæces, while they continue to thicken in the large intestines, which is taken up by the internal hæmorrhoidal veins, from

whence that bitterness, alkalescent, and putrescent disposition of the bile is derived."

It is curious to find that as late as 1823 Adelon in his physiology declaring without hesitation that the blood vessels and the ducts of the glands are continuous without any intermediate organ, the former discharging by their capillary extremities the fluid which is secreted from the blood, only since the blood can no longer reach this point it is no longer called a blood vessel but an exhalant vessel. It was Müller who in 1830 first demonstrated that these two systems of tubes were not continuous. Dutrochet was amongst the first to recognise the importance of the cell, and its structure was studied by Purkinje, Schleiden, Schwann, Henle, Huxley, and Bowman, and in later years by Flemming, Strasbürger, Leydig, Frommann, Hertwig, and many others, with wonderful and far-reaching results affecting every department of physiology.

The labours of C. Bernard, Pavy, and a host of other observers have thrown a flood of light on the functions of the liver and have demonstrated that whilst there may be a conspicuous outward or excrementitial result of the activity of the gland, as in the case of the bile, which has its own purposes to fulfil in the economy, there may also be a not less important internal or excrementitial product, as glycogen, which is entirely concealed from superficial observation, whilst there are organs like the thyroid or adrenals that yield no visible secretion yet exercise a considerable influence on the general nutrition of the body by discharging the products of their activity into the blood. The structure of the kidney and the composition of the urine were not thoroughly understood until the masterly researches of Bowman demonstrated the relation of the blood vessels to the urinary tubuli which were followed by those of Henle on the epithelium of the tubuli. The composition of the urine, to which Haller devotes only a short paragraph, is now accurately known through the labours of innumerable observers in all countries. The influence of the nervous system on the glands has been clearly shown in the case of the salivary, sweat, lachrymal and other instances.

ALBRECHT VON HALLER.
Physiologist, Botanist, Poet. Born, 1708; died, 1777.

Respiration.

The mechanism of respiration was well understood in Haller's time. More than a quarter of a century was to elapse before the normal and abnormal sounds of the respiratory acts were to be rendered familiar to all by Laënnec through the application of the stethoscope. The chemical processes involved in those acts had just been elucidated by the genius of Lavoisier, but his clear exposition of them had not as yet gained entrance into the textbooks. Haller seems to have thought that in the lung substance the small arteries exhaled a plentiful vapour into the cells, whilst the veins absorbed a watery vapour from the same cells. Hence a thin solution of wax could be made to pass from the arteries into the air cells, and from thence to the bronchi; or from the veins into the same spaces, and so to the bronchi; or lastly, from the arteries into the veins, and *vice versâ*, the air cells being thus regarded as the common meeting place and seat of free communication of the minutest arteries, veins, and air tubes. Yet he elsewhere says that in the lungs the "cold air very nearly touches the blood." The unsatisfactory condition of chemistry in the period antecedent to Cavendish and Priestley rendered it impossible to give an intelligible account of the changes occurring in respired air.

So little was the entrance of air into the blood by chemical affinity understood, that it is stated that "no elastic air is here received into the blood as is demonstrated from the impossibility of forcing air into blood if it retains its elasticity, from the inutility of its reception, if the spring of it should be lost, into the blood; from the perfect immutability of the blood by cold; from the minuteness of the inhaling vessels, with the mucus that perpetually lines the sides of the vesicles in the lungs, to which add the nature of the elastic air self, which is very unapt to pass through capillary vessels, with a repulsion of it by water that hinders it from passing paper, linen cloth, or skins that are wetted by water." It is thought necessary to assure the reader that the air being driven into the windpipe never passes the heart, or whenever it does it is forced thither by violence. The effects of the passage of the blood through the lungs on the temperature of the blood was very obscurely stated. It was felt that the warming of the expired air and evaporation of the watery vapour must coo blood: but on the other hand, since arterial blood is warmer than venous, the blood must acquire its heat in the lungs, and in this error even Lavoisier participated. After the above quotation, in which phrases are used only to cover ignorance, let us give the simple and pregnant, but at the time he wrote them perfectly novel, expressions of Lavoisier, about 1776. "Of two things," he says, "one must occur: either the portion of oxygen contained in the air is converted into carbonic acid gas in traversing the lungs, or an exchange of gases takes place in this organ. On the one side oxygen is absorbed, and, on the other, the lung restores a quantity of carbonic acid gas of nearly equal volume." He subsequently read a memoir, in which he maintained that a combustion or oxidation of hydrogen took place in the lungs. Of course

nothing was known of the process of internal respiration, or the exchange of gases between the tissues and the blood.

Animal Heat.

The imperfect knowledge of chemistry led to the wildest guesses at the cause of the high and uniform temperature of the animal body. By many the heart was regarded as the source of animal heat, the blood there undergoing a kind of fermentation; by others it was attributed to the friction of the blood corpuscles against the walls of the blood vessels, and by others again to some obscure influence of the nervous system. The extremely ingenious and careful experiments of Lavoisier led physiologists to juster views. He was even able by means of his calorimeter to ascertain the total quantity produced. At the time the *Primæ Lineæ* were written, though nearly ten years had elapsed from the time when Lavoisier's views were published, they had not received general acceptance, or at least were not taught. Haller's views were not clear upon the subject, and he deals with animal heat very slightly. The chief error of Lavoisier was the conviction that animal heat was generated in the lungs themselves instead of in the tissues of the body at large.

The observations of Hunter and of Dr. John Davy on the temperature of different races of man in various climates, and subsequently of Newport on the temperature of bees, and of Valentin on man, were highly suggestive and instructive. By the use of a thermo-electric apparatus Nobili and Nulloin were able to recognise very slight changes of temperatures. The influence of functional activity on the local temperatures was shown by Ludwig in the case of the salivary glands, and the action of the sympathetic on the vaso-motor system, and its secondary action on temperature by Brown-Sequard and Schiff. Of late years the results of the careful experiments of Frankland, Ranke, Hirn, Helmholtz, Rubner, and others on the heat equivalents of different kinds of food and upon the seats and amount of heat production have shown the uses of applied physiology in providing appropriate and economical food for sailors, soldiers, prisoners, and other bodies of men, both when at rest and when doing work, and also by furnishing a measure of tissue consumption constituting a most valuable aid in the prognosis and treatment of febrile diseases.

Such inquiries also showed and furnished an explanation of the correlation of hibernation and such phenomena as the development of fur and change of plumage according to season in animals with variations of temperature.

Digestion.

Digestion, the details of which occupy so large a space in modern textbooks, was very imperfectly understood. The opinions of Pitcairn who thought that the muscular force of the stomach was equal to 117,088 pounds weight, and was supplemented by an equal force derived from the diaphragm and abdominal muscles; as well as that of Dr. Drake, that digestion is performed in the stomach, as in a Papin's digestor; and that of Cheselden, who held that digestion is no other than corruption or putrefaction of our food, and is performed by a menstruum which is chiefly saliva, were discredited after the experiments of Reaumur and Spallanzani, but it was reserved for Dr. Prout in 1824 to show that the gastric juice contained hydrochloric acid, and for Schwann in 1836 to isolate pepsin. Haller maintained that in fasting the stomach contained a considerable quantity of a limpid fluid or humour resembling saliva, but more mucous, and that the sensation of hunger proceeds from the attrition of the sensitive folds of the lining membrane of the stomach. His account of digestion is as follows: "The aliments taken into the stomach begin to corrupt or change into a nauseous liquid, often ascescent or putrescent, though this is less frequent in mankind from our use of bread and salt, or it may be rancescent, as appears from the flatus and other matters eructated, often of a most fœtid, caustic, and inflammatory nature." From which we may conclude, if the Baron described his own symptoms, that either his food was not very wholesome or his digestion was very bad. He ends with the remark that there is, therefore, no particular kind of ferment in the stomach "from which the design of Nature, the disposition of the stomach and its use, are all very remote."

The chemistry of the digestive processes, almost entirely unknown, as we have seen in Haller's time, has of late years attracted the attention of a multitude of observers, partly owing to the ease with which the fluids can be obtained in a nearly pure state by the formation of fistulæ, and partly from the interest which is excited by the attempt to follow the steps effecting the conversion of non-living into living matter. Tiedemann and Gmelin, Liebig, Strecker, Majendie, Kühne, Bernard, Leuret and Lassaigne. Liebig, Bernard, Chauveau, Colin and Kühne, and Pavy suggest themselves at once as the names of a few only of those who have followed generally the changes of the food in the stomach and intestines, or who have studied the action of the fluids poured into the alimentary canal by the salivary, gastric, pancreatic, hepatic, and intestinal glands. But, perhaps, none made such solid contributions to our knowledge on this subject as Dr. Beaumont, who about 1834 continued his observations for more than a year on a young Canadian who had a gastric fistula from a gunshot wound permitting the digestion of numerous articles of food to be carefully watched. The general result has been to rectify many errors into which the older physiologists fell, and to place our knowledge of the processes of digestion on a sound basis. The earlier changes that the different kinds of food undergo, whether oily, starchy, or albuminous, are now fairly well known, as well as the mode in which they are absorbed, and the channels by which they pass into the blood, though much remains to be done before the assimilation of food can be regarded as thoroughly understood.

The account of the pancreas and of its secretion, given by Haller, constitutes a measure of the advances that have been made in our knowledge of that gland. No account of its structure is given, but the pancreatic juice he describes as watery, insipid, thin, neither acid nor alkaline, and as the gland is three times larger than the salivary glands, the quantity of the fluid it discharges must, he thinks, be considerably greater. Its expulsion, is due partly to the force of the circulating blood, and partly to an alternate pressure from the incumbent and surrounding viscera. Its use is to dilute the viscid cystic juice, to mitigate its acrimony, and mix it with the food. It fulfils every office of the saliva. It need hardly be said that now, after the researches of Claude Bernard, that secretion would be described in very different terms, as highly alkaline, ropy, small in quantity, and acting on starches, oils, and proteids, through the action of different ferments.

Nervous System.

But perhaps no department of physiology has undergone greater and more striking changes than that of the nervous system. It has been attacked on many sides. The scalpel has followed the course of the fibres with the nicest care; all

the methods known to the histologist have been applied to it. Fragments have been separated, hardened immediately upon their removal from the body, embedded in supporting material, cut with sharp knives into the finest sections, stained with one, two, three, or more colouring agents, in acid, neutral, or alkaline solution, affecting differently the various elements; mounted in transparent balsams and examined with microscopic lenses that magnify a thousand times or more the apparent size of objects. Based on the fact that the portion of a nerve fibre remaining continuous with the nerve cell from which it springs preserves its histological characters when the nerve is divided, whilst the distal portion undergoes very obvious changes, fatal to the performance of its function, what have been termed degeneration experiments have been performed by Waller and others; and by the aid of these the course of fibres and the functions of different parts have been determined. The distinctive characters of the anterior and posterior roots of the spinal nerves were ascertained independently of each other by Sir Charles Bell and Majendie. The theory of reflex action was developed by Dr. Marshall Hall. The structure of the spinal cord was carefully investigated by Lockhart Clarke and Schroeder Van der Kolk. Their investigations have been largely extended; and the columns of the cord, in which definite bundles of nerves are united, have been distinguished by Goll and Burdach and Turck and Gowers. This knowledge has proved of great importance in localising disease.

The whole subject of the functions of the brain was of course very superficially known. The functions of the different parts which were anatomically described with sufficient precision, could not even be guessed at as long as the brain and cerebellum were supposed to be insensitive to tactile and other impressions. The high sensibility of the dura mater led to curious ideas in regard to its functions. The seat of the soul was discussed and placed successively in the pineal body, the corpus callosum, the corpora quadrigemina, and even in the liquid contained in the ventricles of the brain; by Haller himself it was more sensibly held to be situated in the crura of the medulla, corpora striata, thalami, pons, medulla oblongata, and cerebellum, and the origins of all the nerves. Nevertheless, the mistaken notion of Malpighi that the cortical substance of the brain is glandlike in structure, and that the fluid secreted is poured into the tubes of the medullary portion, which constitute excretory ducts, was still held.

The nerves were seen to be composed of fibres, and these fibres were known to be continuous with the fibres of the brain. Some indeed thought they were solid threads which, when excited, vibrated and conducted the particular impressions to the brain, but Haller notices their softness, their want of elasticity, and absence of tension, and after adducing various arguments to show that the nerves could not act as vibrating cords, concludes with this remark: "Therefore, upon the whole, it seems to be certain that from the vessels of the cortex a liquor is separated into the hollow pipes of the medulla which are continuous with the small tubes of the nerves, even to their soft pulpy extremities, so as to be the cause both of sense and motion. But there will be a twofold motion in that humour, the one slow and constant from the heart, the other not continual but exceedingly swift, which is excited either by sense or any other cause of motion arising in the brain." Lastly, as the fluid could not be constantly pouring into the nerves, and not overflow, he thinks that it probably exhales through the cutaneous nerves: possibly some may be resorbed and may exhale into the various cavities of the body, as the stomach and intestines.

Of the existence as well as of the advantages of the decussation of many nerves Haller was well aware.

The observations of Hitzig and Ferrier—that stimulation of certain convolutions of the brain was followed by responsive action of various muscles, sufficiently constant to be predicted with tolerable certainty—opened up a new field, with the result, to some extent anticipated by Broca—who indicated the third left frontal convolution as specially dedicated to speech—that certain areas of the cortical substance had as their function the reception of the impressions of the several senses, whilst other convolutions presided over or originated movements of various muscles; and at the present time it is accepted by all physiologists that the occipital lobes are the psychical centres of vision, the temporo-sphenoidal lobes those of hearing and smell, and that the ascending parietal and ascending frontal convolutions proceeding from above downwards are related to the muscles of leg, arm, and face. The functions of the cerebellum still remain to be elucidated.

Some progress had been made by 1800 in the physiology of the special senses, especially of the eye, but perhaps no parts of the body have been of late years investigated during the nineteenth century with such extraordinary diligence and success as these organs. This is evidenced both by the advances that have been made on the purely theoretical side as well as by the improvement in practice that has taken place in the diagnosis and treatment of their diseases by the application of such instruments as the ophthalmoscope.

The subject of muscular contraction has been also pursued with great perseverance. Haller recognised in muscle elasticity, and irritability, the *vis insita*, or, more correctly speaking, contractility and sensibility, but little was known either of its structure or properties. Bowman gave the first full and accurate description of its histology. Krause, Dobie, and others followed. Its composition was studied by Kühne, Brücke, and others, and many articles have been written on the sources of muscular energy, the metabolism that takes place in muscle during rest and fasting, and in full diet and work. The form and rapidity of the wave of contraction has been investigated with special instruments. The phenomena of tetanus and of rigor mortis have been examined, and the action of muscles in various positions of the body and in various movements have been followed out.

Embryology.

Of embryology there is no space to speak; it is enough to say that it constitutes one of the most vigorous offshoots of the parent stem, and that many observers are engaged in the problems it offers to the naturalist.

Applications to Hygiene.

A secondary but by no means unimportant result of the study of physiology has been its practical application to the affairs of daily life. Applied physiology points out the necessity of food that shall be abundant and wholesome, of free supply of water for drink and for ablutions, regular exercise in the open air, good ventilation in houses, appropriate intellectual training for the child, and avoidance of excessive mental and bodily exertion for the adult. The nation that will follow the dictates of sound physiology will have the best developed and healthiest men and women for its constituent units, and will have the fewest hospitals, asylums, and prisons. Disease and premature decay are in a large number of instances the result of the neglect or opposition to the rules of physiology intelligently applied.

Pathology in 1800.

BY D'ARCY POWER, M.A., M.B.OXON., F.R.C.S.,
Assistant Surgeon to St. Bartholomew's Hospital, London.

IT is perhaps difficult to say whether a greater advance in pathology was made between the years 1700 and 1800, or between 1800 and 1900. The workers of the eighteenth century swept away mystical pathology, which owed its birth as much to an ignorance of physics and chemistry as to faulty observation. The workers of the nineteenth century have collected an enormous number of isolated observations, made possible by improvements in physical science, but no master mind has yet appeared to correlate and subordinate these facts, whilst in some departments, notably in pathological chemistry, we have still as much to learn as had our ancestors a century since in the science of chemistry itself.

A hundred years ago modern pathology was in its infancy, but its students had begun to place the new science upon a firm footing of morbid anatomy. The Hunters bequeathed their school and methods to Matthew Baillie, a most worthy disciple and distinguished physician. In 1793 Baillie published *The Morbid Anatomy of Some of the Most Important Parts of the Human Body*, which he illustrated in 1799 by *A Series of Engravings representing every Diseased Change of Structure to which the Internal and more Important Parts of the Body are Subject.* The two books long served as textbooks of pathology, and a short analysis of their contents will best show wherein we have gained knowledge since they were published.

TERMINOLOGY.

The first thing which strikes a reader of the *Morbid Anatomy* is the faultless English in which it is written and the easiness of the style. There are no cumbrous pathological terms; inflammation of the liver is not a hepatitis, nor is dropsy of the kidney a hydronephrosis. A few words differ from those now in use: thus, venous is always "veinal," endemic is "endemial," curdy is "curdly," and tuberculous is, of course, "scrofulous," tubercle being employed throughout in its anatomical sense of nodule rather than in the restricted specific sense it now has. Although Dr. Baillie was Snell Exhibitioner of Balliol College, Oxford, he writes "schirrus," still a stumbling-block to students, and "apthæ"—mistakes which are to be excused, perhaps, by the passage in his autobiography which says: "I went to the Latin School at Hamilton before was quite 7 years old, and remained there six years. The master of the school was named Whale. He was an excellent Latin scholar, but was not very thoroughly acquainted with the Greek, although he had enough of the latter language for the creditable teaching of his school."

The arrangement of the book is essentially anatomical. The matters dealt with are matters capable of being shown by dissection. There is very little theory and there are no generalisations. Baillie, as the nephew, heir, and pupil of the Hunters, often quotes the opinions of his relatives, and always with the greatest respect. John Hunter he speaks of as "Mr. Hunter, an anatomist whose opinion is of great weight," whilst William Hunter is always mentioned as "the late Dr. Hunter." The work is essentially modern in tone, but occasional glimpses are afforded of the time at which it was written, as when arsenic is said to be "the poison most frequently taken," and it is suggested that "every person is acquainted with the appearance of the mucus of the nose when dried," for there were no tests for the mineral poisons, and handkerchiefs were not in general use.

FEVER.

The absence of all knowledge derived from auscultation and percussion makes the chapters upon the diseases of the chest singularly barren, yet Baillie availed himself of such means of physical examination as were then in use. He recommends that "the heat of the internal parts will be most conveniently measured by putting a small thermometer into the rectum." How much he was in advance of his time in this matter is shown by the following passage from the obituary address by his friend and contemporary, Sir Henry Halford, who says: "He appeared to lay a great stress upon the information which he might derive from the external examination of his patient, and to be much influenced in the formation of his opinion of the nature of his complaint by this practice. He had originally adopted this habit from the peculiar turn of his early studies; and assuredly such a method, not indiscriminately but judiciously employed, as he employed it, is a valuable auxiliary to the other ordinary means used by a physician of obtaining the knowledge of a disease submitted to him. But it is equally true that, notwithstanding its air of mechanical precision, such examination is not to be depended upon beyond a certain point. Great disordered action may prevail in a part without having yet produced such disorganisation as may be sensibly felt, and to doubt of the existence of a disease because it is not discoverable to the touch is not only unphilosophical, but must surely in many instances lead to unfounded and erroneous conclusions. One of the inevitable consequences of such a system is frequent disappointment in foretelling the issue of the malady, that most important of all points to the reputation of a physician; and though such a method of investigation might prove eminently successful in the skilful hands of Dr. Baillie, it must be allowed to be an example of dangerous tendency to those who have not had his means of acquiring knowledge, nor enjoyed the advantages of his great experience, nor have learned by the previous steps of education and good discipline to reason and judge correctly."

DISEASE OF THE HEART.

Baillie knew that "when the heart is much enlarged it is attended with palpitations. These may not only be felt by the hand when applied to the left side, but may often be perceived by the eye, even when the chest is covered by the ordinary clothing. In one or two instances I have known the pulse at the wrist to beat with an unusual degree of vigour, but much more commonly the pulse is feeble and irregular. The muscular parietes of the heart being generally very thin in proportion to the enlarged size of its cavities, the heart has little power to propel an increased quantity of blood into the more distant branches of the arterial system. At times there is much difficulty of breathing, and there is a purplish hue of the cheeks and lips. The colour is more deep in its tinge at one time than another, according as the blood has been transmitted with more or less difficulty through the lungs. The causes which produce a morbid growth of the heart are but little known; one of them would seem to be rheumatism attacking this organ, as Dr. Pitcairn has observed in several cases." A thickening and opacity of the semilunar valves and of the valvular apparatus between the auricles and the ventricles are described correctly enough, and when the auriculo-ventricular valves are thickened the heart is said to be "often found to be considerably enlarged beyond its usual size. I have also seen the valvular apparatus between the auricle and the ventricle in a state of inflamma-

tion and covered with a layer of coagulable lymph. This I believe to be very uncommon." He then goes on to say that "the symptoms which are produced by a diseased alteration in the structure of the valves of the heart are not so distinct as to be clearly discriminated in practice. They consist of difficulty in breathing; of occasional palpitations; of a weak and often an irregular pulse; and in some cases there has been observed a disposition to fainting. No observations have yet been made by which practitioners may be led to conjecture what set of valves is diseased."

No Knowledge of Microscopical Anatomy.

The difficulty of pursuing morbid anatomy without the use of a microscope is manifest throughout the book, and it is doubtful whether Dr. Baillie had any clear idea that capillaries nearly always connect the ends of arteries with the beginning of veins. He says, in speaking of blood in the pericardium without a rupture of the heart "blood may have been thrown out by the extremities of the small vessels opening upon the surface chiefly of that portion of the pericardium which forms the intermediate covering of the heart, whose orifices may have been to a very uncommon degree relaxed." In the same manner he thinks that the air found in the stomach may have been "separated from the blood in the blood vessels of the stomach, and poured by the small exhalents into its cavity." The absence of a microscope prevented any knowledge of the minute changes which occur in an inflamed tissue, and caused all hard tumours to be classified together as "scirrhous." Hypertrophy of the prostate, therefore, was called "scirrhous of the prostate," and was not recognised as a disease of old age, whilst uterine fibroids are described as "scirrhous enlargements of the uterus."

MATTHEW BAILLIE, M.D.
Born 1761, Physician to St. George's Hospital 1787-1799, died 1823. (From a print in the collection of the Royal Medical and Chirurgical Society)

The explanation of many pathological processes was made difficult by the teaching that the blood was a living substance in the sense that more active changes took place in it than in the tissues, whereas we know now that the tissues are the more important, and that few pathological changes take place in the blood itself.

Pathological Chemistry.

The backward state of chemistry in like manner prevented any clear subdivision of the diseases of the kidney. Albuminuria was of course unknown, but curiously enough there is no mention of the appearance of blood in the urine. Dr. Baillie had arrived at the conclusion that gall stones "commonly do not consist of inspissated bile," and that white flaky crystals could be obtained after boiling them in spirits of wine. Better results had been obtained with urinary calculi, for the experiments of Dr. Wollaston, the chemist, had enabled them to be grouped into fusible calculi, mulberry calculi, and phosphatic calculi, a basis of classification which is still adopted.

Parasitology.

Dr. Baillie must at one time have been greatly interested in the subject of comparative anatomy, and, acting probably under the guidance of William Hunter, he had made some original observations in connection with parasitic worms. Two great obstacles stood in the way of a true appreciation of the facts connected with them. The one was that the doctrine of spontaneous generation was still in full force and all cysts were spoken of as hydatids, and the other that Baillie knew nothing of the alternation of generations which is now so familiar to us. Under the heading of intestinal worms Dr. Baillie describes the ascaris lumbricoides, or as he calls it lumbricus teres. He had dissected it very carefully, and he compares its structure with that of the earthworm, with whose anatomy he was equally well acquainted, for he even knew something of its nervous system. He also describes the tænia solium and bothriocephalus latus, threadworms, and the trichocephalus dispar or trichuris. Speaking of them he says: "There is nothing in the œconomy of animals more obscure than the origin of intestinal worms; were they found to live out of the bodies of living animals, one might readily suppose that their ovula were taken into the body along with the food and drink, and there gradually evolved into animals. This, however, is not the case; they do not seem to be capable of living any length of time in any situation, except within a living animal body, which appears to be the proper place for their growth and residence. We might, therefore, be led to another supposition, namely, that intestinal worms are really formed from the matter contained in the intestines, which previously had no regular organisation; but this idea is widely different from all analogy in the production of animals where there has been any satisfactory opportunity of examining this production. The origin of such animals is a subject of much obscurity, and I do not pretend to throw any light upon it. When the whole evidence, however, in support of the one and the other opinion is compared together, I own that the grounds for believing that in some order of animals equivocal [that is, spontaneous] generation takes place, appear stronger than those for a contrary opinion."

If he was in trouble about parasitic worms, he was in worse trouble about hydatids, for he says: "The origin and real nature of hydatids are not fully ascertained; it is extremely

probable, however, that they are a sort of imperfect animalcules. There is no doubt at all that the hydatids in the livers of sheep are animalcules; they have been often seen to move when taken out of the liver and put into hot water, and they retain this power of motion for a good many hours after a sheep has been killed. The analogy is great between hydatids in the liver of a sheep and in that of the human subject. In both they are contained in strong cysts, and in both they consist of the same white pulpy matter. There is undoubtedly some difference between them in simplicity of organisation; the hydatid in the human liver being a simple uniform bag, and the hydatid in that of the sheep having a neck and mouth appended to the bag. This difference need be no considerable objection to the opinion above stated. Life may be conceived to be attached to the most simple form of organisation. The probability of their being animalcules is very strong; and it appears even more difficult to account for their production according to the common theory of generation than for that of intestinal worms." Yet knowing this, or perhaps biassed by it, we find the only piece of really faulty observation to which he has committed himself in the following passage in the volume of *Engravings* to which reference has been made above: "A portion of a placenta is here represented which had been converted into hydatids. It had belonged to an ovum which was not far advanced—namely, to about the third or fourth month. It is not uncommon for every part of an ovum except the fœtus to have hydatids formed in it, and these put on a different appearance from the hydatids which grow in the human liver. They are oval in shape, and have a very narrow neck or process running out from one extremity of them. Their coats are thinner than those of hydatids of the liver, and they are not enclosed like them in hard cysts. They possess a procreative power, and smaller hydatids are often to be seen attached to the coats of the larger ones. They appear to have the same claim with hydatids of the liver to be considered as animals of a very simple structure."

General Accuracy with Many Deficiencies.

It is clear from the foregoing extracts that the morbid anatomy learnt by students a hundred years ago was essentially modern in tone, and was for the most part accurate. The curious thing about it was the huge gaps which remained to be filled. Pneumonia and the changes produced by it in the lungs are dismissed very summarily. The lungs are said "to be sometimes converted into a solid substance very much resembling the liver, but I have only seen an example of this change in a preparation, and I am inclined to believe that it had been produced by a wide-extended inflammation, in which a large quantity of coagulable lymph had been extravasated into the substance of the lungs." In the same way emphysema is almost neglected. Dr. Baillie says, "In opening into the chest it is not unusual to find that the lungs do not collapse but that they fill up the cavity completely on each side of the heart. When examined their cells appear full of air, so that there is seen upon the surface of the lungs immediately under the pleura a prodigious number of small white vesicles. The branches of the trachea are often at the same time a good deal filled with a mucous fluid."

There is one passage which may be read to convey a suggestion of typhoid ulcers, for in speaking of inflammation of the intestine he says: "In the follicular glands, which are gathered together in little oval groups, I think ulceration occurs more frequently than in other parts of the intestine."

Students in England were fortunate, therefore, in having so good a teacher as Dr. Baillie, who in turn owes much of the success of his *Illustrations of Morbid Anatomy* to the "drawings made by a young man, who is not only well skilled in his own art, but who possesses a considerable share of knowledge in anatomy." The name of the artist is not mentioned, but on turning to the plates each is signed "W. Clift," first the amanuensis, then the friend of John Hunter, afterwards the faithful guardian of his collection, whose daughter married Sir Richard Owen.

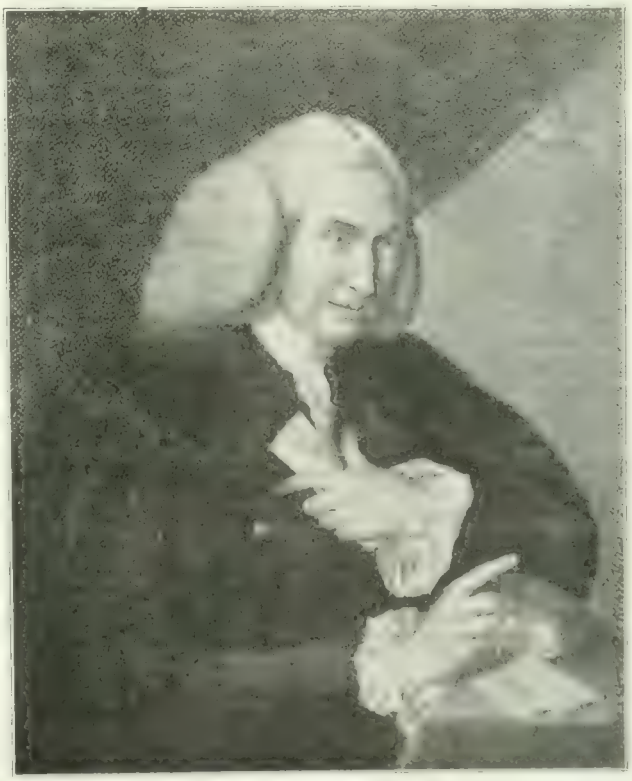
Pathology in Scotland.

At the beginning of the century it was only in England that pathology had become a separate subject. In Scotland it was still combined with physiology and therapeutics under the general heading of "The Institutes of Medicine." Dr. Andrew Duncan in 1782 issued a small volume entitled *Heads of Lectures on Pathology*, but his notes show that he taught upon the old lines, and was dealing with a highly speculative science instead of with one based upon morbid anatomy. The lectures were extra-academical, and attracted a large number of students, but it was not until 1789 that Duncan succeeded to the chair held by James Gregory, whose election he had contested in 1776. The University Chair of Pathology was not founded until 1831, the first professor being John Thomson, father of Professors William and Allen Thomson, but it was not until nearly the middle of the century that any separate textbook on modern pathology was published.

Pathology in Ireland.

In Ireland things were still more backward, and Professor Macalister, in his recent memoir of James Macartney, has given a lively picture of the state of the profession in Dublin a hundred years ago. Macartney transcribed a series of "Opinions Peculiar to Mr. Dease, Professor of Surgery in the College of Surgeons, advanced in his course, 1796." Amongst these Professor Macalister quotes, "the brain is an inorganic mass, devoid of sensibility and irritability, secreted by the arteries of the pia mater, and consequently incapable of inflammation; that polypi in the nose, like other animals, have their infancy, maturity, and death." John Cheyne, however, Professor of Medicine, 1813-19, in the University of Dublin, devoted himself more particularly to the study of pathology, and with the assistance of Dr. Robert Percival, the Professor of Chemistry, established a museum of morbid anatomy in connection with the House of Industry Hospitals.

Medicine in 1800.



By T. CLIFFORD ALLBUTT, M.D., F.R.S.,
Regius Professor of Physic in the University of Cambridge.

The Editor has asked me to describe the state of medicine at the beginning of the nineteenth century, and has pointed out that the works of Cullen are worthy of regard as a monument of that time. Cullen's *First Lines of the Practice of Physic* was published first in 1769, and went through many subsequent editions, until in 1827 an excellent edition of Cullen's works was published in two volumes by Dr. John Thomson of Edinburgh; this edition I have used in the preparation of the present article. Cullen was born in 1712, and died in 1790.

In the history of thought we find that after periods of extravagant speculation, whether in the direction of realism or of mysticism, or indeed of a sounder philosophy of a literary or academic kind, a phase of "common sense" sets in. With this phase, if he come to hear of it, the ordinary man is

delighted, for he thinks that by common sense is meant his prevalent notions; wherein he is grievously mistaken. Common sense is not vulgar sense, nor does it deal in commonplaces; on the contrary, common sense means that which is contrasted with special sense; it is a sense of relative values, a delicate appreciation of many conflicting and contingent facts and principles, so that in the atmosphere of all the ideas concerned each has its own perspective. What may be lost in ingenuity or in passion is gained in breadth of touch, in balance and moderation; and such was the character of the eighteenth century. In times of this common sense then is often a lack of inspiration, nay, even of penetration of the mind; but things are shepherded together, and gains are counted at net values. The bent of such times is to a broad and critical rather than to an intense and creative purpose; and so it was that at the beginning of the nineteenth century criticism was stronger than creation. The kind of creation which distinguishes our own time is that inspired by the experimental method; but this method, although established in physiology by Harvey, Haller, and Lavoisier, did not get into full swing till the latter half of the nineteenth century. The immediate effect indeed of Harvey's discovery of the laws of mechanics in the field of the animal body was at first to impel men not to common sense, but to a vigorous exaggeration of the new point of view: every function was to be regarded as mechanical; and thus arose the "iatro-mechanical school." Under a like impulse, deriving from the chemical discoveries of Boyle and his followers, an iatro-chemical school sprang up. Nay, more strangely still—though by no means without precedent — men turned to opposite extremes or reactions, and from these more positive conceptions swerved off into realism of the most extreme kind, as in the animalism of Stahl, into the refurbishing of old *a priori* principles such as the sthenia and asthenia of Brown, or into mysticism as involved as that of Hahnemann, a characteristic product of Germany. Chemistry, however, was much behind mechanics and hydrostatics, and had not advanced so far as to obtain a ready acceptance for iatro-chemical doctrines; chemical principles, indeed, formed little part of the doctrine, which consisted rather in a preference for mineral before galenical drugs: the cardinal function of respiration, for instance, which might have taken a greater place in the chemical theories of the day, was strangely neglected; even the discoveries of Priestley and Lavoisier were left almost unacknowledged in the institutes of medicine, as we see in the works of Cullen. In Cullen's attitude to his great contemporary, Lavoisier, in his indifference to a revolution in physiology as great as the discovery of the circulation of the blood, the reader may be reminded of the attitude of Bacon to Harvey. For Lavoisier Harvey's discovery had been waiting; without it the function of sanguification was unexplained: yet in Cullen's physiological chapters we find the animal heat referred to the motion of the blood,—not to the friction of the blood, either in its channels or in its own particles, which by some perverseness is deliberately excluded,—and the respiration is deliberately excluded. "The breathing animals," says Cullen, "are the warmest; but that they are warmer because they breathe is not more probable than that they breathe because they are warmer."[1] Herein we see that Cullen was far behind even Boyle and John Mayow, who lived a hundred years before him.

The iatro-chemical school then was in no great vogue in Cullen's day; and Cullen himself was a loyal adherent of the mechanical school. I have said that the impulse given by Harvey to a mechanical physiology was powerful enough to last even into our own century. As might be expected, its chief strength was in Padua and in the other Italian seats of medical learning. In England the iatro-mechanical school never won a firm footing: but Archibald Pitcairn (1652-1713), the author of the *Elementa Physico-Mathematica*, advocated its doctrines in Scotland; and thus may have formed some tradition of the kind in the Chairs of Glasgow and Edinburgh which Cullen successively occupied. But if we may judge from internal evidence, it was rather from abroad that Cullen drew these opinions. Like all physicians of his time he was influenced by Boerhaave of Leyden, though he does not hesitate to contradict his master and to attach himself rather to his disciple, Gaubius, a sensible eclectic physician whose name will enjoy no long immortality.

WILLIAM CULLEN, M.D.
Born 1712, died 1790. From the mezzotint by Valentine Green after the picture by Wm. Cochrane in the Royal College of Physicians, Edinburgh.

Boerhaave's reputation in the first quarter of the eighteenth century has truly been called "stupendous"; perhaps no physician ever enjoyed so great a fashion with so little scientific merit. It is difficult to say wherein Boerhaave benefited medicine save of course by his pursuit of practical clinical teaching in hospital wards: wherein, however, he seems to me to have shown less insight and skill than his pupil van Swieten, and less power of clinical observation than the memorable succession of English physicians, who may be indicated by the eminent names of Sydenham, Friend, Mead, Huxham, Fothergill, and Pringle. However, Boerhaave, chiefly by virtue of his personal character, was a prodigious leader, and reigned alike in the kingdoms of physiology and in medicine, studies

[1] Cullen's Works, ed. Thomson, vol. i, p. 203.

which were scarcely differentiated till our own generation. It is not easy to see that Boerhaave held anything of the spirit of Harvey; he seems to have made no experiments, and, in his writings at any rate, to have contented himself with hashing up the partial truths and the entire errors of his time. He was essentially an iatro-mechanic, and this chiefly on mere reasoning; a bad example. And in the ranks of the iatro-mechanics was a greater than Boerhaave, namely, Frederick Hoffmann of Halle. While Stahl at the same university was proclaiming a doctrine of the soul, as a biological principle, in terms of which Aquinas and van Helmont would have been ashamed, Hoffmann was devoting far greater powers of mind in constructing a theory of life on geometrical methods. Either through Gaubius or more directly, Cullen drew much of his mechanical physiology from Hoffmann. In this view the body is a hydraulic machine: its inward movements cause its heat; by its velocities the blood drives out humours and obstructions; the brain is the centre of tonus, and a nervous fluid permeating the intimate structures carries energy with it; the body is made of a "mixt" of water and gluten ("tissues" were unknown till Bichat's *Anatomie Générale*, 1801) the proportions of which accounted for degrees of elasticity, flexibility, friability, etc. (*debile laxum*, *debile tenerum*, *debile fissile*, etc.) in health and disease; its connective and vascular parts by their pressures govern growth, activity, and death; it observes rhythms, as do other moving masses, hence come critical days and periods, such as sleep and menstruation; in the fluctuations of nervous energy, spasm and atony arise, and are causes of many, and originally, perhaps, of all diseases; fevers and inflammations are directly due to a flogging of parts of the brain or other parts by the rebellious blood, which breaks out into guerilla wars in this region or in that (inflammation and fever); and so forth. All this is, of course, mere ratiocination; of experiment there is not a poor ha'porth. Still Hoffmann saw what Boerhaave did not see; he saw that pathology is an aspect of physiology, a view then novel enough; he did something also for neuro-muscular conceptions, and something more for the circulation in the arteries; but for biological categories—for distinction between life and non-life, for the difference between the organic and the inorganic, for insight into nutrition and secretion—the world had to wait till all these men of principles were supersede d by the men of experimental verification—to wait, in a word, for Bernard. But what of Haller, a brilliant and distinguished man of science, a true experimenter, and a cautious reasoner? Well, although his *Elements of Physiology* appeared in 1757-60, for these forgers of general principles Haller might never have existed! Into Cullen's works some of the Hallerian teaching seems to have found its way by means of the eclectic Gaubius, but of the method and spirit of this great man we discover little. Even Bichat was rather anatomist than physiologist; and, if Haller's inspiration failed to fashion Bichat, we shall look in vain for its manifestation in smaller men. Thus was it that Haller in the eighteenth century always seems to me to have been something of a *vox clamantis;* and I repeat that for the reader of Cullen's physiological lectures Haller might never have existed! This hollowness makes the medical writers of the latter half of the last century and the beginning of this seem farther from us than even Galen himself, in whom, as Dr. Payne has lately reminded us, the true spirit of experimental science was awake.

If Haller was thus neglected what of the equally great Morgagni, whose celebrated letters on the seats and causes of disease were published in 1761, twenty years before Cullen's *Practice of Physic* appeared? An eminent writer says that Morgagni's great work "made pathological anatomy a science, and diverted the course of medicine into new channels." Would that it had! The reader may peruse *Cullen* from cover to cover and fail to find out that Morgagni again had ever existed. As Haller had to wait for Bernard, so Morgagni had to wait for Laënnec and Bright; disciples worthy also in this that, like their great forerunner, they never forgot that, for the physician at any rate, pathology can only be studied profitably in connection with clinical medicine; and thus in them it was preserved from the scholasticism of Rokitansky. Even Matthew Baillie I can scarcely acquit of some forgetfulness of this truth, that only in the combination of the two points of view—the clinical and pathological—can medicine find its safety.

The tendency of iatro-mechanics was, as might be expected, away from spirits and humours and towards solidism. The deposition of Galen's humoralism was an advantage, and the tendency to express living processes in terms of "movements" was wholesome. Of modern molecular physics of course Cullen had no conception, but often he uses the word "movements," in no unscientific manner, of intimate processes far more scientifically than in some modern speculations. The fault of the iatro-mechanicians was not that they pressed mechanical conceptions to their utmost applications, this is a sound use of analysis, but that they argued about them instead of testing them; even Bichat was apt to forget that after mechanical categories are exhausted other categories come in; and that after chemical categories in their turn are exhausted other facts remain, for the interpretation of which neither chemistry nor physics is sufficient—those which for the present we call vital. In a sense fashionable to-day, all these phenomena are at the bottom mechanical; but in my opinion much misunderstanding is caused by extending the word "mechanical" beyond the movement of masses to the movements of molecules and of atoms; that is, from the physical into the metaphysical world. When Cullen and the iatro-mechanical school tried to explain life and disease by mathematical and physical conditions and moments their explanations were not alien but inadequate.

I have said that in the eighteenth century the chemical school had less ascendency; chemistry was then not understood sufficiently well to be used readily in physiological conceptions. In his eclecticism, however, Gaubius dealt a little in chemistry; he attributed certain diseases to "acrimonies"—a word often in use at the time; and he said, not without shrewdness, that vegetables are apt to run to acrimonies (acids), and animal foods rather to ammoniacal putresence, in which opinion Cullen followed him; though Cullen protests against too ready a belief in hypothetical acrimonies. We begin, also to hear of the "cacochymies" with which, under the name of "crases," the school of Rokitansky made so great play. Cullen is not far wrong in declaring that the chemiatrics of his day had become frivolous and hypothetical; that they were not "chaste" enough to avoid baseless speculation; yet in a neighbouring page he does not hesitate to try by ratiocination to ascertain the causes of hunger, thirst, and other organic sensations.

With all its limitations, however, the mechanical physiology made for moderation and discouraged extravagance. As I have said, Cullen is a model of good sense, even in his philosophy. His own hypotheses are set forth with modesty and "chastity." If he asks his hearers to grant him a moment for "*lusus ingenii*," he warns them that they will bestow a few moments upon them at their peril. On the other hand he says well that to profess to avoid all theory is mere talk, and to preach practice without theory is "specious but

impracticable;" every man has his theories, good or bad: weak and ill-trained minds have frivolous or dangerous hypotheses, their facts are as false as their reasons, and they do not know where to stop. Even Sydenham, whom Cullen honours, had his theories, and bad ones too; but he held them, says Cullen, in a light hand, and did not allow them to blind him in practical matters. For, as Cullen goes on to say, mere empiricism is an impossibility—to huddle facts together without organising them is but confusion; we must reason as we observe: yet observation is fallacious, man variable and peculiar; the work of Nature secret and complex, the lack of facts lamentable, and our slavery to words pernicious! Thus, for example, Cullen's criticism of the current teaching on "temperaments" is admirable and characteristic; treat of them he must, but mainly to declare that the whole matter is smothered with the doubtful guesses and untrustworthy descriptions of men who could observe only through the medium of their prepossessions. We are not surprised to find that Cullen leaves little of this fictitious structure standing. Yet while thus positive and shrewd, and thus lamenting the lack of authentic facts, Cullen tries to supply them not by more scientific observation and some experiment, but by more arguments; arguments which differed from those of other teachers only in their greater sobriety. He did not see that in physiology, as in other sciences, by experiment only can a body of law be obtained. For instance, he thinks well of cold water treatment in fevers, and wishes that by a thermometer the method could be made more precise; yet it does not occur to him to try, although Haller had set him the example, he prefers to argue on. In his criticism of the "*vis medicatrix Naturæ*" is an instance of Cullen's "common sense." He points out that although Nature is a moving system, tending to readjustment or disturbance, yet to attribute to this system of causes an intention of cure is no less a vice than to assert that all natural processes are good. He does not hesitate to say this trust in "Nature," if useful in a protestant time, brought weakness and timidity in practice upon Sydenham, as it had done upon Hippocrates himself.

Let us now turn from Cullen's physiology to his *First Lines of Physic*, and see how he treats this subject. The influence of the great Linnæus, then in the ascendant, led his contemporaries to press even to greater extremes the logical classifications which had their origin in the Aristotelian scholasticism; and, like many worse men, Cullen was impressed by the fallacious notion that diseases are susceptible of arrangement into genera and species, as are plants and animals; whereas, of course, diseases are not individuals, but various states of an individual. Being qualities, not things, they can no more be divided into genera and species than, let us say, colours can be.

Cullen divides diseases into two main classes—namely, Pyrexiæ and Neuroses. The Pyrexiæ he divides into Fevers, Inflammations, Exanthemata, Hæmorrhages, and Profluvia. In their observation of fevers—"*morbi sine materia*"—the elder physicians were at their best. Cullen takes intermittent fevers as the type, and remittents as aberrations. Continued fevers are another kind, which he divides naturally enough into the "inflammatory" and the "nervous," by the latter those being signified which, affecting the nervous system, manifest tremor, coma, prostration, etc. For the inflammatory fevers (many of which, as he admits, are symptomatic) he has no causation but his "phlogistic diathesis," of general or local manifestation, a god which he brings out of many a machine. The delirium of nervous fevers he attributes to "an impetus to the brain," though, on remembering that such impetus must occur in violent exercise also, he is a little bothered; but everywhere in such difficulties he not only avoids the hypothesis of toxic influences, but also overtly prefers his mechanical hypotheses as less visionary. He recognises, however, the poisonous effects of overcrowding, as in gaols, etc.; and also those of miasmata (ground effluvia): but, except in gaol fever and in intermittents, he gives them no great part in disease. He notes curiously the comparative immunity of scavengers. Hectic fevers for him denote suppuration. The inflammations are, of course, local rebellions of the blood in this part and that; whether ophthalmias, cynanches, gastritis, hepatitis, nephritis, or the rest (nephritis vera or idiopathica he admits, but dwells chiefly on that due to calculus). He notes that in rigor the temperature is rising, and that constriction of the superficial arteries is a part of the process. He proposes a fanciful debility as the immediate cause of the attack. On pp. 42-44 of the second volume we may find sufficient evidence of the prevalence of diphtheria within the sphere of Cullen's practice.

The class of hæmorrhages is a very heterogeneous one: containing epistaxis, hæmoptysis, hæmatemesis, hæmaturia, menorrhagia, leucorrhœa, piles, etc. Phthisis pulmonalis comes under hæmoptysis, and with this disease he deals in a remarkable way. He contests the wisdom of sending these patients to warm climates, and of coddling them; on the contrary, he recommends plenty of fresh air, if possible by sailing on the sea. Mercury and much bleeding, even in highly febrile stages, he is sure is mischievous. Finally, he tells his pupils that they "will discover nothing satisfactory in books" for the treatment of phthisis, and he wishes he had "the time and the genius" to work out a better treatment. He is clinician enough to be assured that tubercle—a "noxious acrimony"—is almost without exception the cause, not the consequence, of hæmoptysis. He traces phthisis also to dusty occupations, as in stonemasons, flaxdressers, and others. He urges that there is also a kind of phthisis attributable to calcareous deposits, for in some cases he has seen such matter voided from the lungs. For the amenorrhœa due to phthisis, by some "pious and innocent fraud," he was wont to avoid the emmenagogues for which he was generally importuned. Balsams, in his opinion, disorder the stomach, prevent nutrition, and are indeed of little use.

Under hæmatemesis we find in Cullen practically no pathology; liver obstruction is doubtfully suggested, and some ulceration of the stomach supposed to be "possible."

Of pulmonary and cardiac diseases Cullen has little to say that need detain us, and of their pathology he had scarcely a glimmer; in one place he does allude to a hepatiform change in the lung, but of this fact he makes no use. The singular jewel in the chapter is his recorded necropsy, whereby he proved that perihepatitis may simulate a pleurisy. (We must remember that when Cullen published his *First Lines* Matthew Baillie was only about 16 years old.) The discoveries of Avenbrügger are noticed once or twice, but to no advantage; in this respect Cullen was no worse than his neighbours, for not till the genius of Laënnec revealed the methods of physical diagnosis was justice done to the great Viennese physician. The second chief class of diseases—the neuroses—is no less heterogeneous and inconsistent; no less founded on very superficial resemblances and analogies. First come the Comata—apoplexy and palsy. Then the Adynamiæ (consisting in a weakness or loss of motion in function); these are syncope, dyspepsia, hypochondriasis. The third sections are the Spasmodic affections without Fever namely, tetanus, epilepsy, chorea, palpitation, dyspnœa, asthma, whooping cough (recognised as contagious)

pyrosis, colic, cholera, diarrhœa, diabetes, hysteria, hydrophobia. Cullen is at his best in subjects for which a sagacious observation and large experience are most effective. Thus he is well equipped for dyspepsia, which he perceives to be often a secondary affection, for syncope, and the like. Hypochondriacs, he tells us, are not to be driven out of their position by reason or raillery, but by artifice and stratagem. In epilepsy he recommends the ligature of a limb above an aura; he distinguishes those attacks wherein the spasm is partial in its origin, and consciousness usually not lost; and he recognises the evil of repetition of attacks of nervous disease, as tending to a habit.

The Vesaniæ form an important division, and they lent themselves no less then than now to mild philosophisings and literary descriptions. He thinks in mania the control of "awe" is a therapeutical means not to be forgone, and that thereunto "stripes" should be cautiously exhibited; advice for which there was no need. (William Tuke and Lindley Murray called their meeting to found the Retreat at York in 1792, about ten years after the first edition of Cullen's *Practice of Physic*.)

Headache is inserted next by Dr. Thomson from the *Clinical Lectures*. "As a disease," says Cullen, "it is obscure, as a symptom difficult." He objects to attribute it to the "acrimony (acidity as we call it) suspected everywhere, even in the nervous fluid itself." His description of megrim is good, especially of the pulse in this malady; but in treatment he is not so good as he might have been; he mixes simple headache with organic disease of the brain, and satisfies himself with such words as "topical fever." He recommends low diet, cold bathing, and avoidance of debauch and fatigue. Of other divisions, such as Cachexias, Emaciations, Intumescentiæ (including adiposity, flatulence, dropsies, and even rickets); and of Impetigines (including scrofula, syphilis, scurvy, jaundice (he denies "hæmatogenous jaundice" but had for the most part gall stone in his mind) we have not space to treat, interesting as are many of the parts; but the essential confusion of his explicit classification is such that his best paragraphs can only be regarded as *obiter dicta*. As gout must be a "spasm" or an "atony," it appears as an atony of the stomach. On therapeutics Cullen is on the whole negative and pessimist. He does not by any means give up bleeding, but is cautious and sparing in its use; he has seen much harm done by its large and routine use in all kinds of patients, and especially in the convalescence which, after free bleeding, is apt to be delayed by weakness and anæmia. In rheumatic fever he notices this disadvantage, as indeed did Sydenham himself; and he advises the practitioner to be content with woollen clothes and the new "Dover's powder." Of purging he has even less favourable things to say, unless there be a cold and bound belly, from which he thinks some infection may arise. The passions of the mind are be mitigated in illness, a measure which he "leaves to the philosophers, or, if you will, to the divines." He also promotes for good the wholesome conditions of life, urging in the prevention and relief of disease the temperance which he never forgets in his philosophy. Concerning drugs Cullen speaks with the same reticence and mistrust: many are the deceptions to which we are liable in estimating their effects; indeed, he leaves few galenical reputations standing. On the one hand, he feels that art is needed as well as Nature; but on the other, experience did not strengthen his faith in medicine as it was in his day; our feeling is that his patients had an eminently judicious physician who would make few mistakes, but inspire no confident hopes. The divorce of surgery from medicine was unfortunate in Cullen's time, as in all other times; for, in the positive and experimental work of the Hunters and the Monros, surgery was then making the way for the regeneration of medicine. The modern reader of Watson's *Lectures* (published about 1840) may wonder at the vast distance between Watson's standpoint and his own; but in Watson's generation physicians had at least assimilated much of the teaching of the morbid anatomists (Morgagni, Baillie, Bright), and of the great French school of Laënnec, by which the art had been transformed. Out of these materials was built a more comprehensive and scientific method, in which the thought of a teacher of medicine was dictated by likenesses and difference of a far profounder kind than were recognised in the time of Cullen. If to us Watson seems far off, the vista of the half century from Watson backward to Cullen seems so much farther as to carry us not as it were into a previous generation, but into a previous age. Still by his sceptical and cautious temper Cullen prepared the way for the new constructions; thus he sapped the foundation of the old medicine, and dismissed the philosophers. In discussing mental disorders he could not but mention such thinkers as Descartes and Leibnitz, but he calmly says that their systems explain nothing, and if admitted, have no application in medical doctrine. Of the experimental method, of pathology human or comparative, of embryology, or even of evolution itself, Cullen knew nothing; but of the old conceptions, to be destroyed for the new, Cullen proclaimed the emptiness. And one great reform he promoted which is yet far from consummated—he dethroned Disease and set up the Patient; he distrusted systems, and he saw that the only real is the individual. Another example he set which it were well that we should imitate: he thought with vigour, discernment, and accuracy, and therefore wrote with lucidity, proportion, and correctness. *O! si sic nostra!* If Watson's admirable style is at times a little precious, if the labour of his file is sometimes to be overheard, Cullen writes so far better than he. The careless reader of Cullen, who runs and reads, does not know how much had gone to that insight, shrewdness, limpidity, and precision. And, as a summer lightning which is everywhere and yet nowhere, there is within all his reflections a keen sense of humour; but it is the humour of an artist who will not sacrifice his art of perfect expression even for a witticism. Cullen was not a great man, nor even a scientific man in his own sphere; there were many fruitful things even within his reach of which he was too sceptical to see the promise; but he was eminently one of those in whom *initium sapientiæ est stultitia caruisse*. And yet this lucid and temperate spirit had scarcely taken wing when the chimera of the disputatious and disreputable Brown caught the fancy of half Europe. Such is the irony of history!

Lunacy and its Treatment in 1800.

By CHARLES MERCIER, M.B., M.R.C.P.,
Lecturer on Neurology and Insanity, Westminster Hospital Medical School.

IN no department of medicine, perhaps, is the contrast between the knowledge and practice in 1800 and the knowledge and practice in 1900 so great as in the department that deals with insanity. In these days, when county vies with county, and borough with borough, in the erection of palaces, ever more and more magnificent, for the reception of the insane pauper; when the leading idea in the treatment of the insane seems to be to impress them with the splendour of their abodes; when a single slap given to a troublesome lunatic by

an exasperated nurse echoes through the length and breadth of the land, is the subject of magisterial jurisdiction, is solemnly investigated by commissioners, is recorded in Blue Books, and formally reported to the Lord Chancellor and the nation; it is difficult to realise the state of the accommodation and treatment of the insane that existed one hundred years ago.

Chains, Manacles, and Muzzles.

In 1800 the Retreat at York had been established for eight years, and the system of treating the insane with humanity, which Samuel Tuke was thus conducting, aroused a frantic opposition. Pinel's labours were unknown in this country, and Tuke was regarded as more fit to be the inmate than the conductor of an asylum. The number of asylums in England, public and private, was 15; it is now 170. The number of registered insane persons in 1799 was about 10,000; in 1899 it was 106,611. Large numbers of insane persons, for whom there was no accommodation in asylums, were detained in prisons; many more were in workhouses, chained in the cellar or in the garret; fastened to the leg of a table; tied to a post in an outhouse, or perhaps shut up in an uninhabited room, or left to ramble half-naked and half-starved through the country.

Of all the lunatics in the kingdom it was computed (by Sir G. Paul) that one-half were not under any kind of protection from ill-treatment, or placed in a situation to be relieved of their malady. Indeed the lot of those who were merely neglected was enviable indeed beside that of those who were "cared for" in madhouses. These institutions were all conducted on much the same principles, and the curious circumstance to us is, that while some attempts were made to conceal the greatest atrocities, the general routine of barbarity was complacently admitted and upheld, as the necessary, proper, and praiseworthy method of dealing with the insane. The modes of concealing what was too bad to be revealed were not marred by any excess of squeamishness. At the York Lunatic Asylum in 1814 it was discovered that of 365 deaths only 221 had been reported; that a patient having been killed, his body was hurried away to prevent an inquest; that two sets of books were kept, one containing the actual receipts and disbursements, the other a fictitious set of accounts for the use of the governors; and lastly, that when the inquiry was pushed, a wing of the asylum conveniently caught fire, and was burnt, together with several patients and much that was to be inquired into.

As to Bethlem, the authorities took some pains by denial and prevarication to evade responsibility for the worst cases, but for the most part they rather boasted of, than apologised for, their arrangements. The presiding genius was Haslam, the resident apothecary, who seems to have exercised autocratic power, and whose *Observations on Madness*, containing humane recommendations strangely at variance with his practice, were published in 1798. According to his evidence before the Select Committee in 1815, the patients were generally chained to the wall, either with manacles or by one leg or arm. Some of them were chained to the tables and sat there in absolute nakedness the whole year round. One patient, a man named Norris, was secured by an iron collar which was chained to the wall; by an iron frame in which his body was encaged, confining his arms above the elbow; and by a chain from his ankle to his bed, and in this predicament he was kept for twelve years. His treatment was considered by the governors "to have been upon the whole rather a merciful and humane than a rigorous and severe imposition." Haslam swore that this mode of confinement was "decidedly necessary"; and the governors declared that the general management of Bethlem, as affecting the health, the cleanliness, and the comfort of the patients was of a nature creditable to the governors and others concerned in its administration.

In the Lancaster Asylum are still preserved muzzles, chains, girdles, handcuffs, manacles, and leg-locks by the hundredweight, all of which were in use in 1800, and most of which were in use to as late a date as 1840. This was at a time when the Retreat at York had demonstrated for many years that nothing was lost and everything gained by treating lunatics as human beings.

Lunacy Law.

Legal protection for the insane there was practically none. It is true that madhouses, as they were termed, had to be licensed, but the Act of 1774, which contained this provision, provided also that licences should be granted "to all persons who shall desire the same." The commissioners had no power to discharge a patient, however satisfied they might be of his sanity; and although they could revoke a licence, they could not refuse to grant it again when it was applied for, so that their power of revocation was effectually nullified. The commissioners were empowered and required by the Act to visit madhouses, but, as these powers were limited to making a report to the College of Physicians, which itself was impotent to enforce any of their recommendations, they soon ceased to exercise their useless visitorial function. The same admirable Act required for the legal detention of a lunatic an order made by a friend of the patient and a medical certificate. It contained no provision, however, that the certificate should be made by a duly-authorised physician, surgeon, or apothecary, so that certificates could be, and great numbers of them were, signed by unlicensed and unqualified persons, who called themselves apothecaries for this purpose. Again, anyone who styled himself the friend of the patient could sign the order for his admission; the same person who signed the order could, and often did, sign the certificate as apothecary, and the one designation was often as false as the other. Moreover, the keeper of the madhouse could himself sign both the order and the certificate for a person placed under his charge.

The commissioners were fully aware of all these abuses, but they were powerless to interfere. Bill after Bill was brought into and passed through the House of Commons to put a stop to them, but all were thrown out by the Lords, where the opposition was led by that great champion of legality, Lord Eldon. Among those who were chained, manacled, whipped, and kept in nakedness the whole year round were notoriously a certain percentage of sane people. Anyone who was troublesome to his friends or whom it was desired to get rid of, could be seized and taken to a madhouse, from which none had power to discharge him; and, to baffle investigation, the keepers of these dens had a system of bestowing fictitious names upon their prisoners, whose real names were known to their gaolers only.

Corporal Chastisement.

More surprising even than the chains and manacles, the nakedness and other horrors, was the use of corporal chastisement avowedly as a means, not of punishment, but of cure. It was taught that the sentiment of fear is the first, and for a long time the only, means by which the mind of a lunatic can be influenced. "When a maniac fears he commences to reason more justly, to connect certain effects with certain causes, and to judge the future by the past. The appeal to his fears is the first essential step to take in his treatment." Accordingly, a necessary part of the equipment of every

"keeper" was a whip, which he used at discretion, and in Hogarth's pictures of Bedlam the keeper is depicted with a whip stuck in his belt. This practice was still continued in 1800. "Keepers" were allowed, and even encouraged, to retaliate upon violent patients; and even George III, the revered Father of the people, who was rarely spoken of but with slavish adulation, was not only repeatedly put into a strait-waistcoat, but on at least one occasion was knocked down "as flat as a flounder" by his keeper. This was told by an eyewitness to Dr. Paul of Camberwell, who died in 1899.

MEDICAL TREATMENT OF INSANITY.

The medical treatment of insanity was in intelligence and humanity much on a par with the mechanical. Dr. T. Munro, who was physician to Bethlem in 1800, has thus described it: "Patients are ordered to be bled about the latter end of May, according to the weather; after they have been bled they take vomits once a week for a certain number of weeks; after that we purge the patients. That has been the practice invariably for years, long before my time; it was handed down to me by my father, and I do not know any better practice." The venesections were not scamped. In acute mania 30 or 40 ounces were drawn at a time, and this was followed by the application of 20 or 30 leeches to the temples. Sir Everard Home advised that George III should be bled till he fainted, but the king flatly refused this mode of treatment, and the court physician had to content himself with an abundance of leeches. The other remedies employed were hellebore, setons, issues, blisters to the head and legs, opium, camphor, musk, medicated snuffs, ice and snow to the head, and music.

THEORIES OF THE NATURE AND CAUSES OF INSANITY.

As an alternative to the "unnatural and brutish violence," as he calls it, with which the insane were usually controlled, Pargeter insists with great solemnity and force upon the importance of "catching the eye" of the patient, and he relates several cases in which most intractable maniacs were subdued by this simple means. "I suddenly unlocked the door," says he, "ran into the room, and caught his eye in an instant. *The business was then done*; he became peaceable in a moment, trembled with fear, and was as governable as it was possible for a furious madman to be."

Pargeter did not think it possible for the human understanding to advance any other theory of insanity than that of Cullen, that the nervous fluid or electric aura which is secreted by the cerebrum and cerebellum and propelled into the nervous tubules, is capable of manifold variations in quantity, of many alterations in quality, may become thicker or thinner in consistence; and "a certain morbid or irritating principle or quality of that fluid acting upon the brain is the primary cause of insanity,..... but what the specific nature of that morbid quality is it is impossible to conceive, and it will no doubt remain for ever secret."

The causation of insanity lay chiefly in the luxury of the times. "Our ancestors deviated from the regular and temperate manner of life—our grandfathers were therefore weaker than our ancestors ..... their offspring were still weaker than themselves, and we of the fourth generation have scarcely any idea, except what we learn from history, of former health and vigour." In addition to this, "the frequent and immoderate use of tea—long fasting—inflammatory food—turning day into night and night into day—the order of Nature most shamefully inverted—our time ..... is vilely prostituted—every active instrument of health is mutilated and maimed—our bodies become enervated, and our intellectual faculties impaired, and the date of life abridged—it is seriously to be remarked that in this age it is easier to meet with a *mad* than a *healthy* woman of fashion."

So wrote Pargeter, the chief authority upon insanity, in 1792, and if we are inclined to smile at the crudity of his inferences, we may perchance recover our gravity by asking ourselves what opinion our descendants in the year 2000 are likely to hold of the view that insanity is increasing at the beginning of the twentieth century owing to the hurry and rush of life, the increased severity of competition, the crowding into the towns, the spread of education, and the general rise in the standard of living.

Midwifery and Gynæcology in 1800.

By G. E. HERMAN, M.B., F.R.C.P., F.R.C.S.,
Senior Obstetric Physician and Lecturer on Midwifery, London Hospital.

THE progress that has been made in midwifery and gynæcology during the century that is closing, will be most clearly brought out if the reader be invited to look through what at the beginning of this century was a standard work upon the subject. Dr. Thomas Denman was then the leading practitioner in that department; he was an able, well-informed, and judicious man. The fifth and last edition of his *Introduction to the Practice of Midwifery* was published in 1805, and may fairly be taken to represent the high-water mark of knowledge of its subject at that time. In many things it corrected error and improved practice, but it is not the present purpose to dwell on its merits, but rather to point out where it has been left behind. Gynæcology hardly existed then; the word "midwifery," as used by Denman, included the diseases special to women.

PELVIC DEFORMITIES.

Denman's description of the normal pelvis is such that a modern editor, while he might perhaps fill in a little more detail, would hardly erase anything. But when Denman treats of deformed pelves, we find that he was aware that rickets and osteomalacia deformed the pelvis, but there his knowledge stopped. He could say nothing more about a deformed pelvis than that it was deformed. Since his time the pelvic deformities caused by the two diseases he mentions have been differentiated and explained: different varieties of the rickety pelvis have been shown to exist: and many pelvic deformities unknown to Denman have been described, methods for their diagnosis supplied, and their effects on labour analysed. Knowledge always brings power. The knowledge which enables us now to distinguish different kinds of pelvic deformity from one another, and to measure the amount of pelvic contraction, has given us the power of conducting labour with contracted pelvis with a precision of aim and a certainty of successful result impossible to Denman and his contemporaries.

We have realised another advance, curiously predicted by Denman, though not exactly in the way that he expected. Speaking of osteomalacia, he says: "It is far less frequent than the rachitis, but more dreadful in its consequences, which no medicine hitherto tried has had sufficient efficacy to prevent or to cure." A page further on he says, "Yet it is possible, by attending to the secretions, and discovering an excess or defect of phosphoric acid or the like principles, th

deficiencies and exceedings might be supplied or lessened, and perhaps the disease removed together with its effects." We can now, by removing the ovaries, remove osteomalacia, but not its effects. The benefit of oöphorectomy was discovered, not by any *a priori* reasoning such as Denman anticipated, but by the observation that cure followed delivery by Porro's operation.

Urethral Growths and Uterine Polypi.

Going a little further into Denman's book we find him mentioning that enlargement of the clitoris may require removal, and that "excrescences of various forms and sizes" may grow from the bladder, urethra "and about the meatus urinarius"; but of the different conditions that may enlarge the clitoris, and the various kinds of excrescence that may occur about the meatus he seems to have been ignorant. Denman devotes 12 pages to the subject of uterine polypus. Most of them are filled with a description of the operation of tying a polypus, and the relation of cases in which this was done. He tells the reader that "the first sign of a successful operation is the scent of something putrefying." In one of the cases he very candidly and instructively relates, an inverted uterus: and in another, a malignant growth, was taken for a polypus. At the present day a snip of the scissors relieves the patient of her polypus without any "scent of putrefaction." Denman's favourite remedy for prolapse was a globular pessary, which, when once put in the vagina, was left there. He mentions a case in which it was worn without harm, so far as he knew, for fourteen years.

THOMAS DENMAN, M.D.
Born 1733; Physician-Accoucheur to the Middlesex Hospital 1769-1783; died 1815.

Ovarian Dropsy.

The rise and progress of ovariotomy is within the memory of many. At the beginning of the century not only could ovarian dropsy, as it was called, not be cured, but it could not be diagnosed. Denman tells us that it has often been mistaken for ascites, and that "when it is increased to a large size, unless it be of an irregular form, and we are acquainted with the early symptoms, the distinction is very difficult or sometimes impossible." Denman makes no mention of uterine fibroids excepting when assuming the polypoid shape.

Abdominal Palpation.

Denman's practice differs strikingly from that of to-day in his very limited use of abdominal palpation. This no doubt was the reason of his imperfect knowledge of fibroids and ovarian tumours. In his directions for the diagnosis of pregnancy, for the differentiation between true and false labour pains, and of the position and presentation of the child, he gives no instructions as to the examination of the abdomen. He examined it sometimes; for he says: "In a few cases I have known the action of the abdominal muscles so regular and strong that the whole volume of the uterus has been heaved up and down alternately, in such a manner that it was scarcely possible to distinguish between this strange succussion and the proper action of the uterus." But he almost entirely relied upon vaginal examination; his deficient appreciation of the value of abdominal examinations was no doubt due to the fact that as he did not practise it, he was not expert at it. Describing irregular contractions of the uterus in the third stage of labour, he speaks of "the uncertain information we may acquire by the application of the hand to the abdomen." He advises that when the placenta has been expelled the attendant should put his hand on the abdomen to see that the uterus is not inverted; but, he adds, "this method is not always satisfactory." Even in *post-partum* hæmorrhage the only abdominal manipulation that he recommends is "moderate pressure upon the abdomen with a very cold hand." His treatment of this dangerous condition was to get away the placenta by vaginal manipulation, and then give drugs and "cordials," and keep the patient cool and recumbent. How strange it would appear to Denman could he revisit us, and see a modern obstetrician conduct a labour without any vaginal examination! Next to such great things as anæsthetics and antiseptics, hardly any improvement in our methods has brought about better results than the systematic use of abdominal and bimanual palpation.

The Forceps and the Vectis.

The forceps which Denman recommends have their blades covered with smooth and thin leather, which, "without any significant increase of bulk, renders their introduction more easy, and takes off, both in appearance and reality, the asperity of the instrument." The instrument was twelve inches long, and was to be applied over the child's ears. If the ears could not be felt, either because the child was too high or too closely locked in the pelvis, it was improper to use forceps. Denman warmly approved the vectis. He says he knows several gentlemen of eminence, accustomed to use the forceps, who have abandoned it for the vectis, but he has never known anyone accustomed to the vectis who has relinquished its use and resorted to the forceps. Denman lectured at one time in conjunction with Dr. William Osborn, and his opinion about the vectis brought a bitter attack by Dr. Osborn, not only on the ground that the forceps was the better instrument (he plainly said that he believed Denman had never used the vectis), but for the singular reason, as it now seems, that Denman's advice would do

much harm because it was so easy for accoucheurs to use the vectis without their patient's knowledge. Denman had neither cephalotribe nor craniotomy forceps; after perforation his only resource was to pull with the crotchet, fixing this in different places, and pulling till something came, thus getting the head away in bits if it would not come through entire. As to Cæsarean section, if this seemed called for, the question before Denman was not whether Cæsarean section or some other mode of delivery should be chosen, but whether Cæsarean section should be performed at all; whether it was not kinder to the patient, and better, to let her die undelivered than to perform a painful and almost certainly fatal operation.

Puerperal Diseases.

The pathology of eclampsia was in 1805 shrouded in darkness. Its connection with albuminuria was unknown, and it is doubtful whether Denman had a clear idea of the differences between an epileptiform fit and other convulsive seizures.

Finally, the last chapters of Denman's book bring us to realise the most stupendous advance that has ever been made in medicine: the discovery that disease is produced by micro-organisms, and the power of antiseptics to protect human beings from such disease. Puerperal fever was to Denman a fatal disease, presenting clinically various forms (which he made no attempt to differentiate), the cause of which was utterly unknown. It is now certain that this disease can be prevented; although it is unfortunately also true that many women are still attended in labour by persons who either do not know or do not use the methods by which it can be prevented. Since Denman's time anæsthetics have relieved labour of its pain, and by making artificial delivery easier and more frequent have robbed childbirth of some of its danger.

Cæsarean Section.

But the consequences of Lord Lister's discoveries reach far further and are not yet exhausted. The once almost certainly fatal Cæsarean section is the simplest of all abdominal operations. When the surgeon opens the abdomen to remove a diseased part, he can never before exactly tell in what way the disease may have displaced or otherwise altered the parts he will have to deal with; and therefore he may in any such operation meet with some unexpected and formidable difficulty. In spite of this, the percentage of deaths following such operations is very small. No such difficulty attends Cæsarean section. In this operation the operator has to deal only with structures that are healthy and in their natural relations. The terrible mortality of the operation in the past came from septic poisoning, from bleeding, because operators knew not how to sew up the uterus; from the operation being done on patients who were exhausted and their tissues damaged by protracted labour; and from its being done in a hurry, under unfavourable circumstances, and by inexperienced operators. All these causes are preventable, and there seems no insuperable reason why the mortality of Cæsarean section should not be brought down to that of natural delivery. The dream of obstetricians for years has been the abolition of craniotomy. Denman helped to prevent the destruction of the child in a large class of cases by teaching the induction of premature labour. Within the last quarter of a century it has seemed as if the revival of symphysiotomy would render premature labour unnecessary. There is now good ground for believing that in the near future a perfected method of Cæsarean section may relegate craniotomy, the induction of premature labour, and symphysiotomy alike to the past.

Surgery in 1800.

By STEPHEN PAGET, M.A.Oxon., F.R.C.S.,
Surgeon to the West London Hospital, and to the Throat and Ear Department of the Middlesex Hospital.

The teaching of surgery at the beginning of the century is well represented by Samuel Cooper's *Dictionary of Practical Surgery*, an excellent piece of work, comprehending all methods of treatment of surgical cases, and all special surgery, and much physiology and pathology; and enlivened by many little personal touches of humour and of vehemence that are kept out of the textbooks of the present day. Having strength and soundness of constitution, it enjoyed a long life. It was still the best textbook of surgery, more than twenty years after it first appeared. In 1834, when the late Sir James Paget began his apprenticeship, he was told by a friend in the profession that he must possess the *Dictionary*:—

"For your *first year's Library*, let me recommend the last Edition of Cooper's *Surgical Dictionary*, an admirable Book, containing everything, the price about one guinea; you may keep it at home, and refer to it whenever you meet with a *hard* word."

Let us take in order some of the more important articles in the *Dictionary*, and see what were the principles and the practice of surgery about a hundred years ago.

Abdomen.

Cooper follows John Bell's teaching, that the entry of air into the abdominal cavity is not in itself dangerous to life. In any case of protrusion of wounded intestine through a wound of the abdominal wall, he would suture the intestine and return it; he might even, in quite recent cases of wounded intestine without protrusion, dilate the wound of the abdominal wall, "to see whether the part is near enough to be got at." But "when the wounded bowel lies within the cavity of the abdomen, no surgeon of the present day would have the rashness to think of attempting to expose the injured intestine for the purpose of sewing up the breach of continuity in it." He is inclined to operate, in favourable cases, for the cure of fæcal fistula. He would not operate on any case of gunshot wound, or on any wound of the gall bladder. And he does not say a word about operation for internal strangulation, or for any sort or kind of internal obstruction.

Achilles Tendon.

Nothing is said of any operation to unite a ruptured tendo Achillis, and nothing is said of tenotomy.

Amaurosis.

This article, 17 pages long, is a good example of the confusion and vagueness of ophthalmic surgery before Helmholtz invented the ophthalmoscope; we understand the old joke, "Amaurosis is a disease in which the patient is blind, and the surgeon can't see anything." Cooper makes no clear distinction between cases of optic neuritis and cases of disturbed vision from remote causes. He defines amaurosis as a "paralytic affection of the retina and optic nerve;" but he seems to pass without a break from the transient hemianopia of migraine to the worst cases of optic atrophy.

Amputation.

Writing before anæsthetics, he is terribly concerned for the want of more dexterity in these operations:

"The reason of the knife being so badly handled in th part of surgery, may generally be imputed to carelessness, slovenly habits, and fear and confusion on the part of the

operator. There are several egregious faults in the method of amputating, which even many hospital surgeons in this metropolis are guilty of."

Especially, he says, men are clumsy in dividing the bone:—

"In no part of the operation of amputation do operators in general display more awkwardness than in sawing the bone. It is one of the most common remarks of such persons as are in the habit of frequently seeing amputations, that the part of these operations, which a plain carpenter would do well, foils the skill of a consummate surgeon, and few operators acquit themselves well in using the saw."

He emphasises the need of using a linen retractor to the cut muscles, to avoid the "unnecessary, unjustifiable torture" of wounding them with the saw. Of ligatures he says that they are "commonly made of inkle, waxed together with white wax."

Amputation of the Heads of Bones.

Under this curious title he describes the first cases of excision, done by Park, Jeffray, and the two Moreaux, father and son. These earliest excisions were, of course, at a frightful disadvantage. He says of them in the *Dictionary* what he had said of them seven years before in a prize essay:—

"The grounds on which I shall at present withhold my approbation from the attempt to cut out large joints, are the following: (1) The great length of time (many months) which the healing of the wound requires. (2) Even supposing the excision of the knee to be followed with all possible success, is the advantage of having a mutilated, shortened, stiff limb, in lieu of a wooden leg, sufficiently great to induce any man to submit to an operation, beyond a doubt infinitely more dangerous than amputation? I think not."

Antrum Maxillare.

For abscess of the antrum he recommends perforation through, or just above, the alveolar edge. For malignant disease, he describes at great length one case of partial resection by Desault; but would prefer in a similar case only to open the antrum freely and scrape out the disease.

Bronchocele.

"The most famous mode of curing the bronchocele," he says, "is by giving internally burnt sponge, and occasionally a calomel purge, at the same time employing frictions to the tumour itself." He advises that the burnt sponge should be given in lozenges containing 10 grs. each of burnt sponge burnt cork, and pumice stone. It would be of interest, in the present day, to work out the active principles of this lozenge. With regard to operation, he condemns it. Of two operations recorded by Mr. Gooch, one had been abandoned half-way; the other had been followed by secondary hæmorrhage, it had been impossible to tie the vessels, and the patient's life had been saved by digital compression kept up without intermission for a week. Still, he would not absolutely forbid the attempt to save life, either by removal of the gland, or by tying the arteries, in certain rare cases of bronchocele with dangerous obstruction.

"Bronchotomy."

Tracheotomy, which is called bronchotomy, is very carefully described. He commends the operation in cases of a foreign body in the air passages, and in certain forms of laryngeal disease with obstruction. He is not very hopeful of it in cases of "membranous croup;" and he condemns the horrible proposal that it should be performed in cases of extreme chronic enlargement of the tonsils. Artificial respiration, as now practised, was not known to him: and he approves of bronchotomy, with inflation of the lungs, in cases of apparent death from drowning. "It may be executed with a penknife, if no better instrument be at hand; and when the incision has been made, a pair of common bellows will suffice for the inflation of the lungs."

Cancer.

This wise long-sighted article on cancer is one of the best in the *Dictionary:* not for its pathology, which is almost *nil*, and the microscope is not once spoken of, but for its sound practical teaching. He disfavours all caustics, and urges the early removal of the disease. "The operation is always permissible when every particle of the disease can be removed by it. Even large open cancers, if they can be entirely cut away, are often capable of being effectually cured." He is, of course, hampered by the inevitable difficulties of his time; but, within its set limits, his teaching here is excellent.

Cataract.

The prodigious length of the article on cataract, 33 pages long, is in sharp contrast with his indifference to the surgery of the ear and of the throat. The chief diseases of the eye have each their separate place in his system; the diseases of the ear are all dismissed in one article of 9 pages. It was long before Wilde in Dublin, Toynbee in London, Politzer in Vienna; there was no Eustachian catheter, save a futile sort of irrigator passed through the nose, no Politzer's bag, no "Wilde's incision," no sort or kind of mastoid operation; indeed, he does not so much as mention the mastoid. The old reproach held true, that the diseases of the ear were divided into those that could be cured by syringing and those that could not be cured by anything.

"Cirsocele."

In treating of cirsocele (varicocele), no word is said of any operation: only, "other writers have related cases of cirsocele, in which the pain was so intolerable and incurable that nothing but castration could afford the patient any relief." It does not appear from the article that the existence of a varicocele was any bar to naval or military service.

Electricity.

It is hard to realise the amazing uses and abuses of electricity before Duchenne's time. Shocks and sparks were administered on general principles; and had been "tried" in cases of tuberculous synovitis, syphilis, and tetanus. There was no faradic current, no diagnostic use of electricity; men found enough encouragement in Mr. Abernethy's cryptic statement that "electricity has a tendency to promote whatever action or process happens to be going on in a diseased part at the time of its application."

"The electrical fluid, as a topical remedy, has been chiefly confined to the following diseases—namely, superficial inflammation, ophthalmia, gutta serena, deafness, scrofulous enlargements, anomalous tumours, fistula lachrymalis, ulcers, cutaneous eruptions, cancers, and abscesses."

Empyema.

Nothing is said of auscultation or percussion: it was three years before the invention of the stethoscope; but it was five years after Corvisart's translation into French of Avenbrugger's *Inventum Novum ex Percussione Thoracis Humani*. Without these physical signs, the diagnosis and the treatment of empyema stood about where Hippocrates had left them; and the *Dictionary* is melancholy reading here, telling of patients who died, and "were opened," and their chests found full of pus. The operation, as in the time of Hippocrates, was incision, and, in some cases, drainage; no bone was removed.

Fractures.

This article, more than fifty pages long, is full of profitable teaching, and gives a very good account of all special frac-

tures. For the whole treatment of compound fractures it quotes Perceval Pott at great length. For the treatment of ununited fracture, where all else has failed, it describes the operation, first performed by Charles White, of Manchester, on January 3rd, 1760, "to cut down to the ends of the bone, rasp or saw them off, and then treat the limb just as if the case were a recent compound fracture." It quotes, with some approval, four or five cases of this kind; but says that the operation had frequently failed, and had sometimes proved fatal. And, it adds, "a modern proposal has lately been suggested—namely, to pass a seton through the new joint." The operation invented by White was, of course, without any wiring or pegging of the ends of the fragments.

Gonorrhœa.

Cooper dares not decide as to the unity or duality of the venereal poison. "The reader must weigh the different arguments himself." He quotes Hunter, Swediaur, and others to support the doctrine of unity, and Benjamin Bell for the duality; but, for himself, he "waives all attempts to decide the point." Only, he goes so far with the dualists, that he would not for gonorrhœa exhibit mercury, nor do most of the best practitioners:—

"If venereal symptoms do ever follow gonorrhœa, they are so excessively rare, and, I may add, always so imputable to other causes, that the employment of mercury as a prevention would, upon the whole, do more injury than benefit to mankind; and this, even admitting (what, in my mind, has never been unequivocally proved) that the matter of gonorrhœa is really capable in a very few instances of giving rise to the venereal disease."

Hæmorrhoids.

He would not operate for hæmorrhoids, save in very severe cases, after all palliative treatment had failed. He prefers the knife to the ligature, and is opposed to the use of caustics or the cautery. And he condemns the common opinion that hæmorrhoids are of a salutary or critical nature.

Hernia.

In the article on hernia, which extends to fifty pages, many authorities are quoted, and at grea length: Scarpa, Pott, Lawrence, Hey, Astley Cooper, and many more. In the account of the ordinary operation for strangulated hernia it is taken as a matter of course that the sac shall be laid open freely: only, in a strangulated hernia of enormous size, old, adherent, never properly reduced, the stricture should be divided, "but without laying open the hernial sac, or attempting to reduce the parts. The reasons against the common plan are the difficulty of separating all the old adhesions; the hazardous inflammation which would be excited by laying open so vast a tumour; and the probability that parts so long protruded might even bring on serious complaints if reduced." Lawrence's advice against attempting to divide the stricture without opening the sac is approved; so is his advice, if the intestine be gangrenous, not to attempt to unite it over a bobbin, nor to moor it in the wound, but only to dilate the stricture, and to leave the adherent knuckle of intestine to slough. With regard to the "radical cure," it should not be attempted on an irreducible hernia; Cooper quotes Pott's vigorous words:

"I am not unapprised what influence a successful operation or two of this sort has had on the unknowing; but I also know that such accidental successes have emboldened the same operators to commit more than one or two murders in similar cases; and that, from the prevalence of fashion, some of these rupture-doctors have been largely rewarded, when they ought to have been hanged."

But for a suitable case of reducible hernia Cooper would not wholly condemn the "royal stitch," that is, the simple ligature of the sac through a two-inch incision. And he adds, "After performing the common operation for the relief of a strangulated bubonocele, might not this opportunity be taken to learn whether a radical cure would not more frequently be accomplished than is at present the case?" He also gives at prodigious length the arguments for and against a rough and ready radical cure of umbilical hernia in children, by the ligature of sac and skin together.

Hydrocele.

Six methods of radical treatment for hydrocele are enumerated: incision, excision, caustic, tent, seton, and injection. He commends the last, according to Sir James Earle's method—two-thirds of wine to one-third of water.

Intussusception.

In the article on intussusception, "called also volvulus," he reviews and finds useless all methods of medical treatment, and condemns operation.

"If the equivocal and uncertain nature of the symptoms of volvulus were not enough to deter us from undertaking an operation, which under the most favourable circumstances could not fail to be extremely difficult, and imminently hazardous to the patient, the state of the invaginated parts will entirely banish all thoughts of such an imprudent attempt."

Joints.

In an excellent article on the joints, full of practical wisdom, he sets aside a vast number of remedies for tuberculous joints; and chiefly praises rest, and counter-irritation with blisters and issues. He says nothing of the value of extension with a weight; but his other rules of treatment are excellent.

Lumbar Abscess.

As to lumbar abscess (psoas abscess) he teaches that when it must not be left alone it should be treated by Abernethy's method of repeated puncture:

"His method is, to let out the matter, and heal the wound immediately afterwards by the first intention. He justly condemns all introductions of probes and other instruments, which only irritate the edges of the puncture, and render them unlikely to grow together again. The wound is to be carefully closed with sticking plaster, and it will almost always heal."

It is a pity that Abernethy recommended also "other means to promote dispersion of the abscess; blisters kept open with savine cerate, issues, electricity, occasional vomits of zincum vitriolatum."

Mamma.

The successive stages of the operation for removal of the mamma are described very carefully: for, says Cooper, "I could not find, in any surgical book with which I am acquainted, what I conceived to be a proper description of the mode of removing a diseased breast." He insists on the supreme importance of early operation in cancer: the nipple must be removed in all cases, and the skin over the tumour; and the incisions must be carried down "at a prudent distance from the swelling, so as to be sure to remove with the diseased mass every atom of morbid mischief in the vicinity." Enlarged glands are to be removed through a separate incision.

Mortification.

This article of seventeen pages is based for the most part on Larrey's magnificent *Mémoires de Chirurgie Militaire;* and upholds his rule, that "when gangrene is the result of a mechanical cause, and puts the patient's life in danger, amputation ought to be performed, without waiting until the disorder has ceased to spread." The date of Larrey's first operation of this kind is 1796.

Nephrotomy.

"The operation of cutting a stone out of the kidney" is, he states, "a proceeding which, perhaps, has never been actually put into practice." "There is no doubt," he adds, "that stones have often been extracted from abscesses about the region of the kidneys, after their presence has been detected with a probe. But with regard to cutting into the kidney, the deep situation of this viscus, and the want of symptoms by which the lodgment of a stone in it can be certainly discovered, will always be strong objections to the practice."

Œsophagotomy.

It is somewhat surprising to find that this operation was performed, and with success, so long ago as 1738, and again some years later (Goursand, Rolland). Cooper approves of it if a patient were dying of obstruction by a foreign body: "Doubtless the uncertain chance of the operation should be preferred to the certainty of a fatal result." There is no mention of any sort of gastrostomy.

Ovarian Dropsy.

The whole subject of the surgical diseases of the female organs and their treatment takes but a few pages: and these are of no particular value. No word is said of ovariotomy. (The date of McDowell's first operation is 1809.) Uterine polypi, and the chief displacements of the uterus, and their treatment, are noted; but there is nothing, or next to nothing, about the inflammations of the pelvic organs.

Rectum, Cancer of.

For the treatment of "the scirrho-contracted rectum," there is the use of bougies, and the administration of palliative treatment. (The date of Amussat's first colotomy is 1839.)

Spina Bifida.

Cooper describes very carefully Benjamin Bell's proposal to ligature the tumour—"I do not know whether this gentleman ever put the above scheme in practice; but suppose not"—and two cases, one of them successful, treated by Abernethy and Astley Cooper by repeated puncture and pressure. He makes no mention of any method of injection.

Testicle, Diseases of.

This article is mainly taken from Perceval Pott. But in truth it is impossible, at this present time, to understand his account of these diseases; the term "sarcocele" was applied by him to diseases that have long since been defined and set apart.

Tongue, Diseases of.

No mention is made of tuberculous or syphilitic ulceration of the tongue; but something is said of the latter in the article on Venereal Disease. It is probable that in the tongue and in the testicle tertiary syphilis was seldom recognised. "Very malignant" ulcers of the tongue, Cooper says, are sometimes cured by medical treatment. For "true cancerous disease," he advises free removal by the knife, and not caustics. "Cruel as the operation of removing the tongue may appear, we should not hesitate to perform it whenever the disease has made a certain progress and is decidedly of a cancerous nature."

There is no need, and no space left, to contrast the surgical teaching of 1800 with that of 1900. But it may well be doubted whether any of our present surgical textbooks far excel this old *Dictionary of Practical Surgery* in common sense, carefulness, and safe doctrine put in plain words. We have come into vast legacies of facts, and take as a matter of course things that Cooper never had; but that does not prove that we make better use of our opportunities, or have more love of our work, than the men of a hundred years ago.

Sanitary Knowledge in 1800.

By W. H. CORFIELD, M.A., M.D.Oxon., F.R.C.P.,
Professor of Hygiene and Public Health at University College, London
Consulting Sanitary Adviser to Her Majesty's Office of Works.

In order to understand the condition of things from a public-health point of view at the end of last century and the beginning of this, it is necessary to consider briefly the important discoveries with regard to the prevention of disease made during the eighteenth century.

Small-pox.

It was near the beginning of that century that inoculation for small-pox was introduced into this country by Lady Mary Wortley Montague, the wife of the English Ambassador to Turkey, this practice having arrived in Constantinople, it is supposed from Circassia, before the end of the seventeenth century. The advantages and disadvantages of inoculation have been so frequently discussed that it is unnecessary to enlarge on the subject here. That the practice itself became almost universal is a sufficient proof of the general prevalence of small-pox, and also (to quote from a lecture I delivered in Birmingham in 1874)

"Shows us at once, in the most striking manner, the fearful nature of the disease. Here was one of the most loathsome diseases, and certainly the most terrible and fatal disorder to which mankind has ever been subject, and yet people deliberately took the poison of this fearful disease and inoculated their children and themselves with it, and this was done in the last century amongst all ranks up to the Royal Family. Why was this? Every inoculated person became a focus for the spread of the disease, and yet inoculation was to a great extent successful, not in preventing the spread of the disease, but in diminishing the number of deaths from it. What does that mean? There is only one thing that it can mean. If they increased the number of centres from which the disease could spread, and actually did spread, in the most virulent form, and in spite of that the death-rate was lessened, which it was considerably, there is only one conclusion to which we can come, which is that the whole population was so infected by the disease that the multiplication of the centres of infection was a matter of little importance compared with the advantage obtained by getting the disease in the milder form in which it usually appeared after inoculation. Inoculation did spread the disease, because during the periods when inoculation was practised epidemics were more frequent than they were before or have been since; but for all that the death-rate was less. For instance, before inoculation was practised, there were 71 or 72 epidemics every 100 years. During the 63 years when inoculation was practised, there were no fewer than 53 epidemics, which is equivalent to 84 every 100 years. This practice is now illegal, and very wisely so."

Lead Poisoning.

Next came the discovery by Sir George Baker that the "Devonshire colic" was produced by lead poisoning. This disease was very prevalent in that county at the beginning of the century, and was generally attributed to the drinking of cider. Various theories, which we need not trouble ourselves with, were started by different observers to account for such a disease being produced by cider. Sir George Baker, however, recognised the symptoms as those of lead poisoning. He had samples of Devonshire cider analysed and found lead in them, whereas samples of cider from Here-

fordshire, where the disease did not prevail any more than it did in Gloucestershire or Worcestershire, showed no lead. He traced the lead to the use of that metal in the apparatus for making cider in Devonshire, which he describes in considerable detail, showing how the juice of the apples necessarily came into contact with the lead, and he submitted his views to the Royal College of Physicians in a series of masterly papers, the first of which was entitled "An Essay concerning the Cause of the Endemial Colic of Devonshire, which was read in the theatre of the Royal College of Physicians in London on the 29th day of June, 1767."

SCURVY.

Some idea of the excessive prevalence of scurvy among sailors in the eighteenth century may be gathered from the statement of Sir Gilbert Blane in his account of "The Progressive Improvement of the Health of the Royal Navy at the end of the Eighteenth and beginning of the Nineteenth Century," to the effect that Dr. Lind, the Physician to the Haslar Hospital, had informed him that in one of the years of the American war "there had been sent on shore from the Channel Fleet in the course of four months 6,064 men, almost all affected with fever or scurvy, and that on another occasion after a ten weeks' cruise 2,500 men were brought into port ill of scurvy." This terrible disease was prevented by the use of lemon juice. This had already been recommended by John Woodall in his work entitled *The Surgeons' Mate; or Military and Domestic Surgery* (1639), in which he says, speaking of the cure for scurvy, "The use of the juyce of lemmons is a precious medicine and well tried, being sound and good; let it have the chief place, for it will deserve it." After some directions as to how and when it is to be given, he adds: "In want whereof use the juyce of limes, oranges, or citrons, or the pulpe of tamarinds." Later on in the seventeenth century lemon juice was occasionally supplied to merchant ships, but its use was not generally adopted.

Dr. James Lind in his *Treatise on the Scurvy* (second edition, 1757) describes some experiments which he made with different remedies on patients suffering from scurvy, and says: "The most sudden and visible good effects were perceived from the use of the oranges and lemons, one of those who had taken them being at the end of six days fit for duty; the other was the best recovered of any in his condition, and being now deemed pretty well was appointed nurse to the rest of the sick." Dr. Lind also recommends the use of onions for the prevention of scurvy.

Lemon juice was ordered to be supplied to the Royal Navy in 1795. The result of this Sir Gilbert Blane, writing in 1830, describes as follows: "The scurvy has been prevented, subdued, and totally rooted out by the general use of lemon juice, supplied for the first time at the public expense in the year 1795; and which operated so speedily that in less than two years afterwards it became extinct, and has remained so," and he adds later on, "by this the scurvy has been so entirely eradicated—or, rather, prevented, that there are now surgeons in the navy of long standing who have never seen a case of it; and it has been already mentioned that in less than eighteen months after the general supply of it Lord Spencer did not find a single case of it in Haslar Hospital."

No wonder that in his *Observations on the Diseases of Seamen*, 3rd edition, 1803, he wrote: "The introduction of this article (lemon juice) may therefore be considered as an æra in the internal œconomy of our navy."

In the meantime Captain Cook had performed his famous first voyage round the world. He started in 1772, and it took three years and eighteen days. During this voyage he only lost four men, three by accident and one by phthisis, out of 118 sailors. The secret of Captain Cook's success in keeping his men healthy is to be found in the journal of his last voyage to the Pacific Ocean, 1776 to 1780, in which occurs the following statement:

"From the time of landing our brewers began brewing; and the woods affording plenty of spruce, the crews of both ships were supplied with this wholesome beverage during our continuance at New Zealand, and for several weeks after we were at sea. This liquor was found so salutory that it seemed to strike at the very root of the scurvy, and left not the least symptom of it remaining about any man in the ships.

"Indeed, great care was taken to supply the crews daily with plenty of scurvy-grass and wild celery to boil with their portable soup, and salt meat was withheld, and fish substituted in its room."

To Captain Cook is no doubt due the credit of showing how to carry out long voyages under healthy conditions.

JAILS AND JAIL FEVER.

Typhus, or jail fever, which had produced the "Black Assizes" at Oxford and other places during the sixteenth century, when (according to Sir Gilbert Blane) Francis Bacon (Lord Verulam) "pointed out clearly that this was a production of filth accumulated by the long neglect of the persons of the prisoners," was extremely prevalent during the eighteenth century, when it even attacked the army and navy.

It is due to the labours of John Howard, who was appointed High Sheriff of Bedfordshire in 1773, that the shockingly insanitary condition of the overcrowded prisons in this and other countries was thoroughly investigated and made public, with the result that an Act was passed in 1774 for the improvement of the health of prisoners and the prevention of jail fever, and that improvements in the sanitary conditions of the prisons in the United Kingdom have gone on ever since, so that now there is not only no jail fever, but the late Sir Robert Rawlinson used to say that from the sanitary point of view a prison was "the best place in England for a man to live in." It must be remembered that enteric fever, which was endemic in some jails, and notably in Milbank Prison, was then considered to be a form of typhus fever.

VACCINATION.

The last great sanitary discovery of the eighteenth century was that of vaccination for the prevention of small-pox, made by Edward Jenner in 1795, and published by him in 1798. The results of this discovery were so thoroughly brought out in this JOURNAL in a number published in 1896,[1] that it is not necessary to refer to them again, so I will merely content myself by pointing out that so far from small-pox decreasing as an epidemic disease during the last century, as has been stated, the five most severe epidemics of that century all occurred in the latter half of it, and the most severe one of all in 1796. Of course, as is always the case, the death-rate of the next few years was much smaller, as, after a great epidemic like that, which caused no fewer than 184 deaths out of each 1,000 deaths from all causes, the number of susceptible persons in the population is very much diminished.

DISEASES OF OCCUPATIONS.

In the year 1703 there was published at Utrecht a most remarkable book entitled, *De Morbis Artificum Diatriba*, by Bernardino Ramazzini, the Professor of Medicine in the University of Padua. The book was translated into English by Dr. Robert James (author of the *Medicinal Dictionary*, and compounder of the celebrated "Fever Powders" which are still called by his name), and was published in London in 1746,

[1] BRITISH MEDICAL JOURNAL, May 23rd.

under the title of "*A Treatise on the Diseases of Tradesmen*, to which they are subject by their particular callings, with the method of avoiding and treating them." This treatise consisted of 43 chapters, and Chapter I., "Of the Diseases of Metal-Diggers," begins as follows:—

"The various and numerous diseases produced in artificers by the exercise of their respective trades are, in my opinion, derived principally from two causes, first, the noxious quality of the matter on which they work, and which, by breathing out noxious steams and subtile particles offensive to human nature, gives rise to particular diseases, and in the next place certain violent and disorderly motions and improper postures of the body, by which the natural structure of the vital machine is so undermined as gradually to make way for violent distemper."

Then follow chapters on the Diseases of Gilders, Surgeons, Chemists, Potters, "those who work in copper and tin," Glass-makers and Glass-Grinders, Painters "such as work upon Brimstone," Blacksmiths, "such as work in Lime and Plaister of Paris," Apothecaries, "Clensers of Jakes" (privies), Fullers, etc., etc., including Tobacconists, Midwives, Nurses, Masons, and Bricklayers, Fishermen and Mariners, "such as stand when they are at work," "such tradesmen as sit much," "of the Diseases of the Jews," Couriers or Runners, "those who work upon Minute Things which strain the Eyes," "Music-masters, Singers, and Others of the like Professions," Husbandmen, which begins, of course, with the quotation from the "Prince of Poets":

O fortunatos nimium, sua si bona norint
Agricolas.

"Of the Diseases usual in Camps," and lastly, "Of the Diseases of Learned Men," to whom he apologises for including them among working men, and about whose diseases he writes an excellent chapter. Early in it he points out the frequency of dyspepsia in the following words:

"All the Men of Learning used to complain of a Weakness in the Stomach. Celsus says (Lib. I, Cap. II): A great many of the Inhabitants of Cities and Towns, and almost all the Lovers of Learning, have Weak Stomachs. There is no hard Student almost but complains of his Stomach: for while the Brain is employed in digesting what the Desire of Knowledge and the love of Learning takes in, the Stomach cannot but make an imperfect Digestion of the Aliment, because the animal Spirits are diverted and taken up in the intellectual Service."

And at the end he sums up with the following advice:

"'The Professors of Learning ought therefore to pursue the Study of Wisdom with Moderation and Conduct, and not to be so eager upon the Improvement of their Mind, as to neglect the Body: They ought to Keep an even Balance, so that the Soul and the Body may like Landlord and Guest observe the due Measures of Hospitality, and do mutual Offices, and not trample one another under Foot.'"

An Early Form of Watercloset. (Reproduced from Sir John Harington's *Metamorphosis of Ajax*.)

There is also a Supplement consisting of twelve short chapters on the Diseases of Printers, Writers and Amanuenses, Confectioners, and various others. The chapter on Diseases of Writers and Amanuenses is remarkable from the fact that the symptoms of Writers' Cramp are described in it.

In order to compile this epoch-making treatise, Ramazzini, as he tells us in his Preface, "thought it no indecency to step sometimes into the meaner Sort of Workhouses, and view the Secrets of Mechanic Arts," and alluding to the directions of Hippocrates as to the questions a physician should ask when he visits a patient, he says: "To which I would presume to add one Interrogation more, namely, *what Trade he is of*."

Hospitals.

The subject of military hospitals and the "cure of camp diseases incident to soldiers" received considerable attention during the last century, the most important treatise on it being Dr. Richard Brocklesby's *Economical and Medical Observations* (1764). In this treatise he urges the advantages of temporary sheds as hospitals. The first instance he gives he describes as follows:

"In October, 1758, a greater number of sick, as before hinted, were landed out of the transports on the Isle of Wight than all the spare outhouses, barns, and empty cottages which could be procured for money or the sake of humanity at Newport were capable of containing. In this distress some gentlemen of the hospital proposed to erect a temporary shed with deal boards upon the open forest, and to have it thatched over with a coat of new straw thick enough to keep out wind and rain, and capacious enough to hold one hundred and twenty patients or upwards, for doing which and the use of the boards the country workman, who was undertaker, exacted forty pounds. Although the hovel was finished in a fashion the most slovenly, and apparently inadequate to the end proposed, upon trial it was found that, notwithstanding much extraordinary cold as well as moisture which the sick there lodged had suffered, remarkably fewer died of the same diseases, though treated with the same medicines and the same general regimen, than died anywhere else, and all the convalescents recovered much sooner than they did in any of the warmer and closer huts and barns hired round Newport, where fires, and apparently better accommodations of every sort could be provided for them."

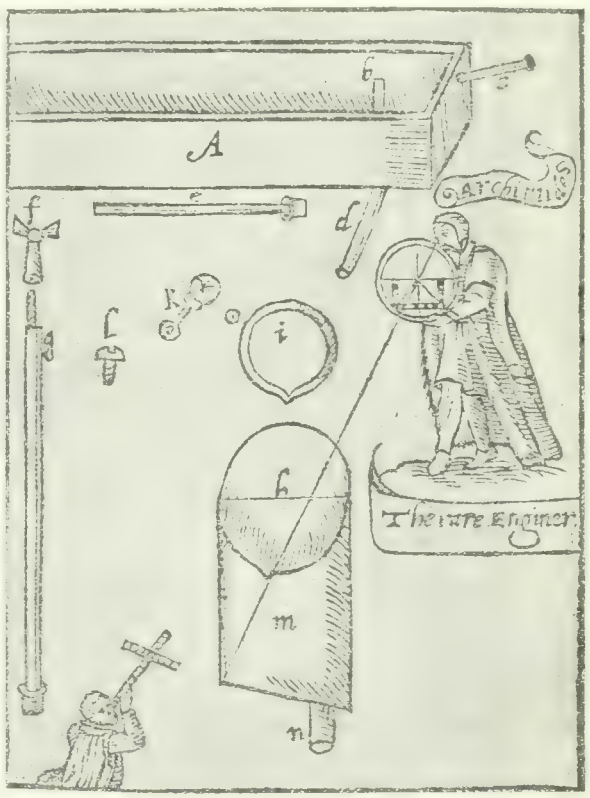
A little further on in his treatise he says:

"I had a further opportunity to prosecute my inquiry about this matter, in the second campaign afterwards, in the year 1760, when a dangerous putrid fever made its appearance amongst the sick of the thirtieth regiment at Guildford, in Surrey, in their infirmary, which was remote from camp about five miles. This place for the sick was crowded with more

than four times the number it ought to have contained; therefore, on my first visiting the house I strenuously remonstrated against that pernicious practice of huddling so many sick in so closely confined a place."

He then selected a spot upon Sand-Heath near Ripley, and erected a temporary hospital there at a trifling expense with the result "that though several soldiers were admitted into this repository ill of a true petechial jail fever, only one or two at most died in it, and I candidly ascribe their fortunate escape more to the benefit of a pure keen air they breathed therein every moment than to all the medicines they took every six hours or oftener."

In the next year he did a similar thing at Winchester Camp where



"Three such mansions for the sick were erected, with all speed, at about two hundred yards in the rear of the camp, and air holes in the thatch, to be occasionally opened, served instead of windows at proper distances. All men in fevers whom I judged it safe to remove were immediately admitted into them from the close infirmary at Winchester, as well as from the camp. And the effect in less than a fortnight was to reduce the number in proportion as four to one, and soon to reduce these numbers (twenty-four in hospital) to less than half-a-dozen. In this manner matters went on to the very end of the campaign, with much fewer sick than ever they had before, and all the men admitted there were cured, except three at most."

Yet another instance:

"The following year, 1762, the like method was followed on the chalky soil of a different encampment, and the sick were parcelled out in small field hospitals, constructed upon the abovementioned plan, with the addition of a large airing porch before each hospital door, for the sick, who could crawl out occasionally, to breathe untainted air, as well as to eat their meals in it; one of the three regiments likewise which was encamped there, and now persuaded to this plan, lost not a man during the whole encampment."

Memorandum the ſcale is about halfe an inche to a foote.

VENTILATION.

During the eighteenth century the ventilation of public buildings was much more attended to than it had been previously, and a ventilating fan, for either extracting or propelling air, was devised by Desaguiliers, and applied to the ventilation of the House of Commons. A method for the ventilation of ships by means of pipes connecting various parts of the ship with the ashpit of a fireplace, and so causing air to be extracted by means of the fire or fires, was also devised by Mr. Samuel Sutton, and was adopted in the ships of the Royal Navy and in some buildings.

WATER PIPES.

The water mains under the streets were made of trunks of trees, with holes bored through them longitudinally, so as to form pipes; one end of each was tapered and pushed into the other end of the next pipe, which had an iron band round it to prevent its being split. Such pipes are still not infrequently dug in the London streets, and specimens of them may be seen at the Parkes Museum of Hygiene.

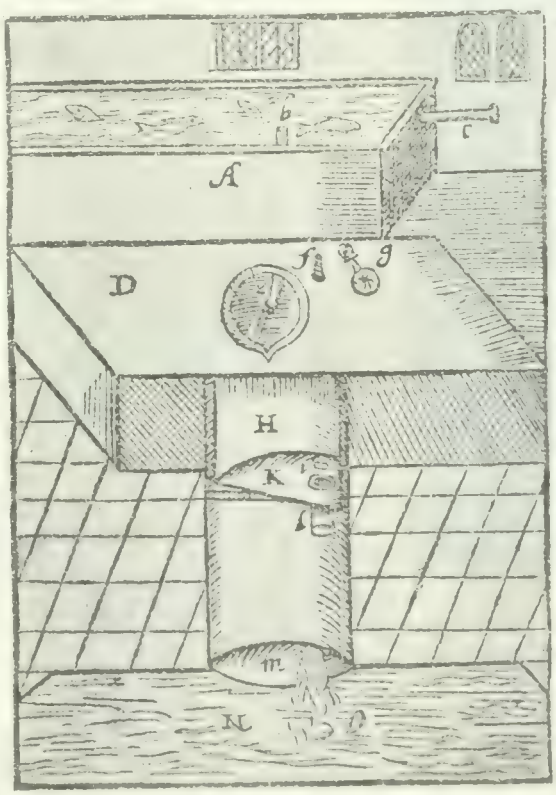
SEWERS AND DRAINS.

The drainage arrangements of towns and houses in the year 1800 were still in a very primitive condition. Pipe drains had not been yet invented, and the drains and sewers were consequently made of bricks or stone. As they were originally intended to carry off surplus water, they were made to discharge into the rivers, after their prototype the *Cloaca Maxima* of Rome. The excremental refuse of the houses was collected in cesspools or middens, in many cases under the houses themselves, and with overflow drains discharging into the drains or sewers of the town, although this proceeding was forbidden.

WATERCLOSETS.

But it was in the eighteenth century that the use of watercloseta in this country began. It is quite true that an appliance of the nature of a watercloset, by which the excremental matters were removed by the use of water, was adopted in the palace of the Cæsars at Rome and in other buildings in that city.

It is also the fact that an apparatus of this kind was devised by Sir John Harington, the learned translator of Ariosto, and was described in detail by him in a work now of extreme rarity, entitled, *A New Discourse of a Stale subject called the Metamorphosis of AJAX*, and printed in 1596. In this rare book are to be found drawings representing the apparatus, which he styled "A Priuie in Perfection," (1) in parts, (2) fitted together ready for use, and (3) in use, by a learned divine in college cap and gown. These three engravings are reproduced here from a copy of the work in the writer's collection, together with the following quaint verses referring to the third of them:



A godly father sitting on a draught,
To doe as necde, and nature hath vs taught,
Mumbled (as was his maner) certain prayr's,
And vnto him the diuel straight repayr's:
And boldly to reuile him he begins,
Alledging that such praiers are deadly sins
And that it shewd, he was deuoyd of grace,
To speake to God, from so vnmeete a place.
The reuerent man, though at the first dismaid,
Yet strong in faith, to Satan thus he said.
Thou damned spirit, wicked, false, and lying,
Difpairing thine owne good, and ours enuying:
Ech take his due, and me thou canst not hurt,
To God my pray's I ment, to thee the durt.
Pure prayr assends to him that high doth sit,
Downe fals the filth, for fiendes of hell more fit.

It will be noticed that fish are shown in the water tank to indicate that it contains clean water, and that the overflow or "wast" pipe of this tank is shown as a warming pipe, and is not continued down into the cesspool, as was so often done in later times.

But, as has happened with many other inventions, the watercloset had no chance of coming into general use until it was patented and someone was interested in bringing it forward. This was done by one Alexander Cumming, who devised and patented an apparatus in 1775, and this apparatus was improved a few years afterwards by Bramah, the forerunner of our present valve closet.

A Priuie in perfection.

Here is the fame all put together, that the workeman may fee if it be well.

And this being well done, and orderly kept, your worft priuie may be as fweet as your beft chamber. But to conclude all this in a few wordes it is but a ftanding clofe ftoole eafilie emptyed.
And by the like reason (other forms and proportions obferued) all o- other places of your houfe may be kept fweet.

The Teaching of Hygiene.

Of teaching of public health in our medical schools in 1800 there was none, which is hardly to be wondered at considering that it has only become a recognised subject of general medical education during the last few years; but in 1807 a successor appeared to the celebrated *Regimen Sanitatis Salerni* of the sixteenth century in the shape of a work written by the Right Honourable Sir John Sinclair, Bart., "founder of the Board of Agriculture," entitled *The Code of Health and Longevity*, or *Rules and Principles for, first, Preserving Health, second, Prolonging Life, and third, Curing and Alleviating Diseases, with Directions for appropriate Diet and Regimen*. This book is a most interesting and important treatise, and in the edition published in 1830 the subject is divided into chapters with the following headings, and with various subdivisions:

I. Air. II. Liquid Food. III. Solid Food. IV. Digestion. V. Exercise. VI. Sleep. VII. The Passions. VIII. Dress or Clothing. IX. Habitation or Place of Residence. X. Travelling. XI. Residence in Foreign Climates. XII. Customs and Habits which Influence Health. XIII. Bathing. XIV. Means of Preventing Accidents or Common Disorders. XV. Education and Management of Children. XVI. Professional Occupation. XVII. Marriage or Connubial Connections. XVIII. Amusements; and XIX. Advantages to be derived from Knowledge and Science.

In the section of the chapter on Digestion, which treats of the excretions, he refers to the experiments of Sanctorius, the learned physician of Padua, who during the seventeenth century devised a balance by which he was able to determine, among other things, the amount of the perspiration.

This book, originally published in Latin under the title of "*Ars Sanctorii Sanctorii de Statica Medicina Aphorismorum Sectionibus Octo Comprehensa*," was translated into English first by Abdiah Cole in 1663 (under the title of "*A New Art of Physick, contained in Eight Sections of Aphorisms concerning Insensible Perspiration, being a Vapour or Breathing from the Body*, Plainly shewing that Health and Sickness is best discerned by Weighing the Body"), who associated his name with that of the author as if they were joint authors, and altered "I" into "we" in the "Address to the Reader;" secondly, by "J. D." in 1676, under the title of *Medicina Statica, or Rules of Health, in Eight Sections of Aphorisms:* and lastly by John Quincy, M.D., in 1720. In his Address to the Reader, as translated by "J. D.," Sanctorius says: "It is a thing new, and not before heard of, in Medicine, that any one should be able to find out the exact weight of insensible perspiration, nor has any one of the Philosophers or Physicians attempted the doing of any thing in that part of the Medical Faculty. I am the first that has essay'd it, and (if I am not mistaken) brought the art to perfection, by reason, and the experience of thirty years." The engraving of Sanctorius in his chair is here reproduced from an edition of his work published in Latin in London in 1701.

Sinclair's book concludes with three chapters of Appendices, the last (Chapter XXII) giving accounts, with portraits of all of them, of eight "persons who attained extraordinary ages," from Isobel Walker, 112 years, to Petratsch Zortan (or Czartan), a Hungarian, who is said to have died at the age of 185 years. To give an idea of the detailed way in which he treats the various parts of his subject, I may mention that in Chapter XV. on the Education and Management of Children, he

discusses their food, clothing, air, exercise, amusements, habits, health, personal appearance and behaviour, mental

Sanctorius in his Balance.

information, and, lastly, moral and religious instruction. Sir John Sinclair's book was, in fact, the first systematic work on hygiene of the nineteenth century.

The Poor Law in 1800.

By J. MILSON RHODES, M.D.,
President of the Poor-Law Unions Association of England and Wales

Great as the progress of the Poor Law during the nineteenth century has been, in no department has the progress been greater than in that portion dealing with the sick poor. During the first third of the century the condition of the sick poor was deplorable in the extreme, whether looked at from the old or the new Poor Law point of view.

Even Thomas Carlyle, who was no admirer either of the "Old Poor Law" or new Poor Law, very properly describes the "Old Poor Law" as founded "on unthrift, idleness, bastardy, and beer drinking." In the earlier part of the century there was no Central Authority, either Poor-law Commissioners or Local Government Board. The consequence was that only now and again, when Parliament, becoming alarmed at the ever-increasing burden of paupers asked for statistics, could any clear idea of the state of the country as regards "pauperism" be obtained. The overseers of every parish had the power to do what was right in their own eyes; and very peculiar those ideas of right were.

In some of the large towns, like Manchester and Liverpool, "select vestries," or similar administrative bodies, had been established, and had placed the administration of the Poor Law on an improved basis; but still the condition of the sick poor throughout the whole country was miserable in the extreme.

A bad system of Poor-law relief, accompanied by bad laws, had resulted in the utter demoralisation of the poorer classes of this country. That the assertion is no mere figure of speech is proved by the statistics of the time showing the enormous amount of pauperism existing in the first year of the century.

Returns called for by Parliament in 1801 show that, out of a population of 9,000,000, no fewer than 1,000,000 were paupers; roughly speaking, 12 per cent. were burdens on the State. At the commencement of the century war and famine had raised prices to an enormous extent; how heavy the burden upon the ratepayers was may be judged from the fact that the relief of the poor cost in the year 1811 no less than 17s. 6d. a head of the population. To-day, with all our improvements, the cost is only 7s. 2½d. a head.

Enormous as this expenditure was, it certainly did not provide proper medical relief for the poor. Even after the passing of the Poor Law Reform Bill, out of an expenditure of £4,600,026, upwards of £254,000 was simply wasted upon the Law of Settlement and Removal, and only £147,000 was spent on medical relief; so that £100,000 less was expended on the "sick poor" than was expended on useless law costs and the often cruel and dangerous removal of sick and sometimes dying paupers.

In considering the Poor Law of the first half of the century it is necessary to remember that the term "workhouse" was to a great extent a correct description of an institution that is now—with the exception of a few "test houses"—becoming almost extinct. Everyone acquainted with modern Poor-law institutions is well aware that the so-called "workhouse" is really a hospital, an asylum, an almshouse, and a school. The real "able-bodied pauper," especially the "outdoor adult able-bodied pauper," who used to be known as the "roundsman," and who was the *bête noire* of our forefathers, is disappearing from the scene, and now only exists as "a sad memory of a melancholy past." Even so late as 1843, out of 88,000 indoor paupers, only 10,000 were classed as sick, and only 146,000 out of 365,000 outdoor patients were so described.

If these figures are compared with statistics of to-day, they prove an enormous improvement in the economic condition of the people. The vast majority of present-day adult paupers are suffering from mental or physical disease—an altogether different class from the able-bodied, idle vagabonds that constituted a large part of the paupers in the earlier years of the century.

How horrible the state of affairs in some of the workhouses was, even as late as 1838, is proved by the records of the Poor-law Commissioners. Dr. Southwood Smith describes the condition of affairs in the Whitechapel Workhouse in the following words: "I was struck with the fact that out of 104 children resident in the House 89 had recently been attacked with fever. On examining the dormitory in which these children slept, my wonder ceased; in a room 88 feet long, 16½ feet wide, and 7 feet high, with a sloping roof rising to 10 feet, live 104 children, together with 4 women who had charge of them slept. The beds are close to each other; in

all the beds there are never less than 4 children, in many 5. The ventilation of the rooms is most imperfect. I was likewise struck with the dull and unhealthy appearance of a number of children in the same workhouse, in a room called the infant nursery; these children appeared to be from 2 to 3 years of age; they are 23 in number, they all slept in one room, and they seldom or never go out of this room, either for air or exercise. Several attempts have been made to send the children into the country, but a majority of the Board of Guardians has hitherto succeeded in refusing the proposal."

"In the Whitechapel Workhouse there are two fever wards. In the large wards the beds are much too close. Two fever patients are placed in each bed; the ventilation is most imperfect, and the room is so close as to be dangerous to all who enter it, as well as most injurious to the sick. The privies in the workhouse are in a filthy state, and the place altogether is very imperfectly drained; there is not a single bath in the house"; and Dr. Southwood Smith sarcastically adds to the report "these facts are the more remarkable because before I went over the house it was represented to me as being in all respects in a very excellent state." It is only right to state that the Whitechapel institutions are really now in an excellent state.

Fever then, was like the poor, always present; in one year three of the medical officers in two London unions were struck down with typhus fever. At another workhouse a room 55 feet by 8 feet by 6 feet found accommodation for 28 young men who slept 5 in a bed. In the young women's ward 16 beds were considered sufficient for 64 young women to sleep in. One of the dormitories was over the washhouse, and usually it was filled with steam; when it is added that there was not 100 cubic feet per head, the condition of things in this ward, which was used for women and children, can be imagined. The sick wards never exceeded 10 feet high, half of them being only 8 feet; no wonder that the report adds "the wards were close and foul." Anyone who has studied the literature of the times will find similar and worse reports than those quoted.

Bad as the provision for the sick poor was, the remuneration of the medical officers was equally so. The Act of 1834 had extended the areas for which the so-called "parish doctor" was responsible, while the system of remunerating him for his services was one that certainly did not lend dignity to the profession. Before the report of the Select Committee on the Poor-law Amendment Act, 1838, it was the custom to advertise for tenders from medical men, and the lowest tender for drugs and attendance was accepted. The Committee did not approve of so degrading a system, but from the report it is very evident that a miserable cheeseparing system existed. Some of the tenders must have been low indeed, judging from the evidence, and, if the result was that the drugs were not of the best quality, as was stated by some of the witnesses before the Committee, it can hardly be wondered at. I find in the evidence that Mr. Rumsey proposes and Dr. Kay supports the proposal "That the scale of remuneration to union medical officers should be about 6s. 6d. or 6s. per case." Mr. Rumsey supposes that this would be about double the present amount of remuneration! The first-named gentleman was then Secretary of the Provincial Medical and Surgical Association, and he strongly advocated before the Committee the appointment of a Medical Commissioner to act with the other Poor-law Commissioners in matters concerning the medical relief of the sick poor. It was not to the credit of the Commissioners that they declined to support this recommendation. That there was ample need for it is proved by the fact that so miserable was the payment to the medical officers that even in 1844, though a great improvement had taken place, yet still the remuneration received by 2,680 medical officers in England and Wales only amounted to £124,532. As the amount expended for the same purpose last year was £397,000, and the number of paupers was little more than one-half what it was then, there has been some increase in the scale of remuneration, but it must be confessed that in a large number of cases there is still room for improvement.

The conditions under which the medical officers of that time worked, and the slums into which they had to go, appear to have been, if possible, more horrible than those which exist at the present time. In Manchester there were in 1844 4,443 cellar habitations containing upwards of 18,000 people. How the people existed may be imagined from an official report, which shows that there were in these cellars

Fever cases were continually on their books; in Manchester, in the year 1838, the deaths from epidemic diseases amounted to 1,924; the number was nearly equal to one-third of the total number of deaths. As a very considerable number of these deaths took place in the workhouses the unnecessary burden cast upon the ratepayers must have been enormous. Bad as the condition of the physically sick poor was, the condition of the mentally sick was, if possible, worse.

Lord Shaftesbury, in his evidence before the House of Commons, gave a horrible description of the imbecile wards. His evidence as to the state of affairs in one of the large workhouses was terrible. He described the patients as being many of them chained like dogs to the wall, and usually left from Saturday night to Monday morning to sleep on a bed of straw, with no food provided for them but a jug of water and some dry bread. Some of these places were ventilated and lighted simply by apertures in the wall destitute of glazing. The wretched imbeciles were often very meagrely clad: in many cases in a state of absolute nudity; and the "keepers" often of the lowest and most brutal class.

Since the close of the first half of the century, when Lord Shaftesbury and his friends took up the question of How to Raise the Working Classes, enormous improvement has taken place. Many of the readers of the British Medical Journal will remember the splendid work done by Mr. Hart, when he was on the staff of another medical journal, in drawing attention to the horrors that existed in far too many of the workhouses in England, not only in the small unions but also in the metropolis; the three greatest improvements in the administration of the Poor-law have come from the Midlands and the North.

To the Chorlton Union belongs the honour of establishing the first pavilion hospital on modern lines for sick paupers, and it may be of interest to some of the medical profession to know that when the plans for that hospital were submitted to the Poor-law Commissioners of that time they were met with the remark, "You do not surely expect your ratepayers to pass those plans;" the reply made by the then clerk to the guardians was, "You pass them and we will meet the ratepayers." To the honour of the ratepayers of the Chorlton Union be it said they have always supported the guardians in making proper provision for the sick poor, and the example they have set has happily to a great extent spread throughout the length

and breadth of the land, and many of the union hospitals are now fully equal to the voluntary hospitals.

To Liverpool must be given the credit for reforming the system of nursing in workhouses. Half a century ago the total number of so-called nurses employed in the 591 unions was 171; their salaries amounted to £2,161, a sum equal to about one-third of what was then expended upon workhouse porters. The whole credit of the reform is due to Mr. William Rathbone, who, suffering from typhoid fever, found so much comfort from trained nurses that he offered for three years to pay the cost of providing them for the Brownlow Hill Hospital; the system of course succeeded, though one of the most eminent authorities at that time expressed the belief "that it was worth trying, but she did not think it would succeed."

Of all the reforms effected in relief of the sick poor during the century, that in my opinion is the greatest.

To Birmingham belongs the honour of properly providing for workhouse children by establishing their cottage homes at Marston Green.

No doubt many reforms are still required, but looking at the condition of affairs in the earlier years of the century, and that existing now, we may look forward with hope and courage to the coming century as one that will see the relief of the sick poor based on a satisfactory footing both as regards the sick poor themselves and those under whose care they are placed.

Military Medicine in 1800.

It should perhaps be explained that the term "military medicine" is intended to include the applications of the healing art in all its branches to the special needs of fighting men whether they serve their country by land or sea. For this extended use of the word "military" we have the authority of that great naval expert, Captain Mahan of the United States Navy, and it is fully justified by its philological propriety not less than by its practical convenience. The Navy is the senior of Her Majesty's two military services. Hence it is fitting that it should have the first place in the following sketch.

Naval Medicine.

If in 1800 the surgeons of the British Navy were not skilful in their profession, assuredly it was not for lack of experience. Most of them had seen the effects of hard knocks and of epidemic disease in its worst forms in various parts of the world. Splendid work in preventive medicine had been done by some of them in the latter half of the closing century. James Lind, who had spent some of th early years of his professional life in the navy, and who was physician to Haslar Hospital till his death in 1794, was indefatigable in his efforts to improve the health of seamen. The conditions under which they lived on board ship may be gathered from Lind's statement that "the number of seamen in time of war who die by shipwreck, capture, famine, fire, or sword are but inconsiderable in respect of such as are destroyed by the ship diseases and by the usual maladies of intemperate climes." This was written in 1774 in the "advertisement" to the third edition of his *Essay on the Most Effectual Means of Preserving the Health of Seamen in the Royal Navy*, the first of which was published in 1757.

Scurvy and its Ravages.

The most destructive of the ship diseases to which Lind refers was scurvy. "This disease alone," he wrote in the preface to his famous *Treatise on Scurvy*, which saw the ligh in 1754, "during the last war proved a more destructive enemy and cut off more valuable lives than the united efforts of the French and Spanish armies." Lord Anson, in his great voyage of circumnavigation, lost four out of every five of his ship's company by scurvy in two years. It was the narrative of the sufferings of his crew that moved Lind to write on scurvy. In the preface to his treatise he says: "It was acknowledged that the best descriptions of it are met with in the accounts of voyages, but it was regretted that those were the productions only of seamen, and that no physicians conversant with this disease at sea had undertaken to throw light upon the subject, and clear it from the obscurity under which it had lain in the works of physicians who practised only on land." Lind himself had had considerable experience of scurvy at sea, particularly in two Channel cruises in 1746 and 1747, and had tried many plans of treatment; but the result of all his experiments was that "oranges and lemons were the most effectual remedies for this distemper at sea" Lind did not claim the credit of having discovered the virtues of the fruit juices which he recommended; indeed, he says: "These fruits have this peculiar advantage above anything that can be proposed for trial, that their experienced virtues have stood the test of nearly two hundred years." In proof of this statement he quotes B. Ronsseus, who wrote in 1564, and according to Lind was the first writer on the subject, as saying that "in all probability the Dutch sailors had by accident fallen on this remedy when affected with scurvy on their return from Spain loaded with these fruits, especially oranges."

Lind's work on scurvy was soon translated into French, and his teaching was at once accepted by the medical profession throughout Europe. But it is written that no man is a prophet in his own country, and there is hardly to be found in history a more striking illustration of the truth of this aphorism than the indifference with which Lind's advice was received by the British Government. The case is cited by Mr. Herbert Spencer as an example of the "amazing perversity of officialism." But it would be difficult, were there not the clearest evidence in proof of the fact, to believe that even the most red tape-bound official could have failed to see the importance of the matter. While scurvy was slaying our sailors by thousands, making our fleets useless, and threatening to undermine our sea power, the Admiralty, with the means of prevention actually in its hands, remained impassive like the gods of Lucretius. In 1780 Admiral Geary had to return to port with 2,400 men of the fleet disabled by scurvy. Fifteen years later Lord Howe almost lost his fleet in the Channel owing to the same cause. This at last aroused the naval authorities from their apathy, and—two hundred and fifty years after the remedy was discovered, and nearly half a century after one of the chief medical officers of the Government had demonstrated its efficacy—they issued an order that a regular supply of lemon juice should be furnished to the navy.

This order was issued in 1795, a year after the death of Lind. The reform was doubtless due to the influence of Sir Gilbert Blane, who in that very year had been appointed Chief Officer of the Navy Medical Board. What Lind did has been well set forth by Sir John Simon in the following words: "The fact that scurvy, which used to cripple fleet after fleet, and to waste thousands on thousands of the bravest of lives, has.....become an almost forgotten disease is due emphatically to Lind; and to him therefore, even thus far, we owe such saving of human life as probably to no other one man except the discoverer of vaccination."

"Ship Fever."

Even this service however, great as it is, does not exhaust Lind's claims to the eternal gratitude of those who go down to the sea in ships. He studied with close attention the epidemic diseases which in his day frequently raged on board ships, and he was able to furnish conclusive proof of the truth of Sir John Pringle's doctrine of the identity of typhus with "jail" and "ship" fever. He published the results of his investigations in *Two Papers on Fevers and Infections*, which appeared in 1763, and in *The Jail Distemper and the Proper Methods of Preventing and Stopping its Infection*, which was issued two years later. Lind's work in this field of preventive medicine may again be summed up in the words of Sir John Simon: "The system of rules which he laid down for limiting its ravages in ships and populous establishments is one to which our after-times have made little or no material additions, and to which we no doubt are in great part indebted for our comparative freedom from epidemics of typhus."

An Era of Naval Sanitary Reform.

Endeavours had been made, with the help of contrivances invented by Stephen Hales (1741) and Samuel Sutton (1742) to find a remedy by efficient ventilation for the "putrid" air of ships, and Captain Cook, in his report on *The Method taken for preserving the Health of the Crew of His Majesty's Ship The Resolution during the late Voyage Round the World*, for which the Copley Medal was awarded to the great explorer by the Royal Society in 1776, had shown how by obedience to the elementary laws of hygiene it was possible even in those days, with a company of 118 men, to perform "a voyage of three years and eighteen days, throughout all the climates from 52° North to 71° South, with the loss of only one man by a disease." At the close of the century the spirit of naval sanitary reform had its most active embodiment in the person of Sir Gilbert Blane. He had served with distinction as Physician to Lord Rodney's Fleet in the West Indies during the last three or four years of the American war, and his mind was so impressed by the amount of disease believed by him to be preventable, which he had seen among seamen, that he set himself seriously to the task of finding means of prevention. In 1780 he issued to the flag officers and captains of the fleet a circular containing instructions as to the preservation of the health of their men, the treatment of the sick, and the checking of invasions of disease. This, he says, "was extremely well received," and he was doubtless thus encouraged to attempt the bold task of enlightening the official mind. At any rate in the following year he laid an elaborate scheme of naval sanitary reform before the Board of Admiralty, following up the attack with a further memorial in 1782. Blane also placed the fruits of his experience before the medical profession in a work entitled *Observations on the Diseases of Seamen*, which was published in 1785. Soon afterwards he was appointed Commissioner for Sick and Wounded Seamen, and Chief Officer of the Navy Medical Board under the Admiralty, positions which gave him the opportunity of carrying into effect the reforms which he had advocated. Of this opportunity he availed himself to the full extent of his lights. Simon ranks Blane with Mead, Pringle, and Lind as one of the most effective of the early promoters of modern preventive medicine.

Dr. Munk, in his *Life of Sir Henry Halford*, tells a curious story which illustrates at once the confidence the Government had in Blane and the condition of the medical department of the sister service in the early years of the present century. In 1809 Sir Lucas Pepys, then President of the Royal College of Physicians of London, as well as Physician-General to the Army and President of the Army Medical Board, was ordered to proceed to Walcheren to report on the grievous sickness which caused such havoc among the troops in that ill-starred expedition. The Physician-General, however, refused to undertake this duty on the extraordinary ground that he was not acquainted with the diseases of soldiers in camp or in quarters! Blane was then asked to go, and when he had sent in his report of his mission the question of remuneration caused the Government not a little perplexity. Lord Palmerston, then Secretary for War, applied to Sir Henry Halford for help in the difficulty. Halford's reply, which is characteristic in its combination of Turveydrop like stateliness with practical sense, is worth quoting. He writes:

"It is difficult to appreciate satisfactorily Dr. Blane's services under the circumstances which your Lordship states; but as you do me the honour to write to me confidentially, I will tell you what I think without reserve.

"I should suppose that £1,500 would be a liberal remuneration, without risk of being thought a prodigal one. It is not material to the case how much or how little inconvenience the Doctor might sustain in his private affairs by his absence at Walcheren: nor do I allow it to bias my judgment that he knew he was to encounter some personal hazard by his attendance on the sick there; a physician should never consider that, but the occasion was an extraordinary one. He obeyed the directions of the Commander-in-Chief instantly, and *his patient was an army*.

"In this point of view, I really think Dr. Blane's reward should be one of magnitude, though I admit that the public purse should be opened on all occasions with more caution and reserve than that of an individual, and particularly at this time."

Naval Surgery.

The average naval surgeon at the end of the last century was probably "in a professional respect" not very far above the level of those of whom Smollett, who had himself been surgeon's mate in a line-of-battleship in the middle of the century, has left immortal pictures. He was less coarse in his habits, and a good deal better educated, but he stood comparatively low in the social scale. It was not indeed accounted a part of his duty to shave the ship's company, as was the case in the service of some other countries. In his *Curiosities of Medical Experience*, Dr. Millingen records the fact that for refusing to act as barbers to the crew some English surgeons who had joined the Swedish navy were summarily dismissed the service. This was in 1801. Tonsorial operations appear to have been included among the duties of Portuguese army doctors in the Peninsular war, for Millingen says that so late as the year 1809 one of his assistants in the Portuguese army felt much hurt at his declining his offer to shave him. But though the surgeons of the British navy held, as may be gathered from Marryat's novels, a fairly good position among their brother officers, it is clear that they were respected for their personal qualities, not for their rank. The popular estimate of them at a considerably later period is seen in a review of Barry O'Meara's *Voice from St Helena*, published in the *Quarterly Review*, in which the writer speaks with insolent scorn of the author's low class in life. As late as in 1831 an order was issued that naval officers were not to presume to present themselves at Court levees; and though the offensive order was speedily rescinded, the mere fact that it should have been made may be taken as a proof of the humble position in the social hierarchy which was assigned to surgeons of the navy even at a time within the memory of persons still living. Indeed, in the medical profession itself the navy was not regarded with much favour as a career if we may judge from a remark attributed to Abernethy. When

Richard Owen had completed his studies and went to take leave of his teacher Abernethy, the latter asked him what he proposed to do. Owen, who had been a midshipman in the navy, replied that he thought of going to sea again, whereupon Abernethy declared that he might as well go to the devil!

EXAMINATIONS FOR ADMISSION TO THE NAVY.

An amusing account of the examinations which some candidates, at any rate, for admission to the medical service of the navy had to pass at the beginning of the present century, is given by Dr. Bozzi Granville in his *Autobiography*. Dr. Granville was an Italian whose mother was of English descent. After a variegated career he determined to enter the British Navy. He had received a regular professional training in the University of Pavia, and, as he boasts, was the holder of a diploma signed by "Scarpa, Rasori, Frank, Borda, Moscati, and Volta, under the great sigillum of the goddess of Liberty and the inscription of 'Repubblica Italiana.'" The following is his account of the examinations which he had to undergo for the position of Assistant Surgeon on board a British warship in 1807:

"Admiral Robert Montagu directed the medical officers of Haslar Hospital to examine me as to my being qualified to serve as assistant surgeon, which operation accomplished, and a certificate of my fitness obtained, the admiral confirmed Captain McKinlay's nomination to the same vessel, dated May 25th, 1807, the day after the examination. The medical officers at Haslar were Dr. Hope, Dr. Magennis, and Mr. Vance. The latter gentleman became in after-years well known in the metropolis, where he settled as a physician, acquiring great reputation as a successful practitioner in complaints of the stomach, for which he used to prescribe certain famous pills, known under the name of Vance's pills. It was my lot, when it came to my turn to practise in London, to meet him in consultation, and later to commiserate, in common with the rest of the profession, the sad and singular fate he met at the hands of an insane patient he had just visited in the upper floor of a house in Sackville Street, who threw the doctor over the bannisters to the bottom, killing him on the spot.

"At my examination at Haslar none of the gentlemen spoke any other European language than their own. Of that language I was then, if not completely ignorant, at all events little able to understand more than a few words or an expression or two picked up during the very short time I had been on board the *Raven*, the surgeon of which ship, a Mr. Francis Johnstone, a Scotchman, spoke Latin with a certain facility and a pronunciation analogous to that of the Italians. Indeed, our own official intercourse on board had been carried on in that language as the only possible means of communication. And so it was the case at the Haslar examination, to which Mr. Johnstone had accompanied me, suggesting that it should be conducted in that language, a task which Drs. Hope and Magennis undertook, Mr. Vance interpolating now and then a few practical surgical questions, which were translated to me into Latin by the other two examiners, Mr. Vance possibly not feeling himself competent to employ the more learned language.

"Whilst noticing here the first difficulty I encountered on English ground, and which was thus overcome, I must not omit to add that it was followed by more than one of the same sort during the first twelve months of my professional experience in this country. I allude to the number of times I was subjected officially to medical examinations, for having not long after been transferred from the *Raven* to the *Millbrook*, a war schooner with a sliding keel invented by Sir Samuel Bentham, carrying sixteen sixty-four pound carronades on a flush deck, commanded by a Lieutenant Leach and a sub-lieutenant, with an assistant surgeon only, I felt naturally anxious to make my appointment a permanent instead of a temporary one. To attain this object it was imperatively necessary that I should appear before the London naval authorities to prove my fitness for the office. Presuming myself sufficiently acquainted with the English tongue, to which I had applied myself in the meantime, I obtained leave to go up to London to present myself before the Transport Board, by whom I was directed to the Royal College of Surgeons to be examined for the rank of permanent assistant surgeon in the navy. This examination was followed by another before Dr. Weir, Medical Commissioner of the Transport Board, on which occasion I obtained my first parchment warrant (now called, I believe, a commission) as a regular assistant surgeon in the Royal Navy, dated November 21st, 1807. Then again in less than ten months I was examined before the same two public bodies for the attainment of my full rank of surgeon, which was conferred on me not long after on my appointment to His Majesty's sloop of war *Cordelia*, Captain Kennedy."

An idea of the way in which those old medical examinations in Latin were conducted may be obtained from a description given by Granville of his examination before the President and Censors of the London College of Physicians in 1817. He had, he says, as companions in the adventure two remarkable fellow candidates, namely, "the surgeon who had received the last words and sigh of Nelson on board the *Victory*, and a Doctor Armstrong, author of a treatise on fever which had created quite a *furore* among the profession, and had secured an enormous practice to its author, for which latter reason he was pulled up by the Censors, and made to come before them for his licence." Armstrong was, however, rejected, not from malice, nor because he was almost entirely ignorant of the Latin language, but for gross ignorance of anatomy and physiology. Dr. Paris told Granville some time after, that Dr. Armstrong had failed to answer almost every question as regards the internal organisation and functions of the body, although the examiners patiently waited a considerable time after every question. "At last," said Dr. Paris, "I thought of one of the simplest possible questions that should give him a chance to come off well, and so I asked, '*Dic, mihi, domine, ubi locatum est hepar?*' '*In corpore, domine,*' was the immediate reply! (Where is the liver placed? In the body, sir.) '*Satis est,*' exclaimed the president, 'you may retire, sir,' and he was accordingly not admitted."

It is gratifying to read that "Nelson's surgeon," doubtless Dr. Beatty, "passed and became an M.D."

THE MEDICAL SERVICE OF THE ARMY.

An interesting sketch of the evolution of the medical service of the army is given in the *Autobiography* of Sir James MacGrigor, who was Principal Medical Officer under Wellington in the Peninsula. From the year 1747, he says, when a warrant of George the Second created an Apothecary General "perpetual furnisher, with remainder to his heirs of all the medicines necessary for the general service of all the land forces in Great Britain," an authoritative precedent was established for "a system of monopoly, exclusive patronage, and collusions in the Army Medical Service, prejudicial alike to the army itself and to the interests of the public." The monopoly created by this warrant appears to have been to some extent infringed at a later period, for till the close of 1796 the surgeon of each regiment, aided by a surgeon's assistant, received a sum proportioned to the strength of the corps, on the condition that he supplied all the necessary medicines. A regulation was then made that the medicines should again be provided by the Apothecary-General, while the pay of the surgeons was increased, obviously with the object of indemnifying them for the loss of the profits which they had previously made on the drugs supplied. In 1794 a Medical Board was constituted for the administration of the medical affairs of the army, and this was a distinct advance, though a wide field was still left for abuses. The Board was composed of a Physician-General a Surgeon-General, and [an] Inspector-General of Hospitals.

Each of these members exercised an exclusive and independent patronage over one branch of nominations and promotions. By the regulations laid down in 1798, it was the province of the Physician-General to nominate to office all the physicians of his department, and to inspect the medicines furnished to the army by the Apothecary-General, whose accounts he had to control jointly with the Surgeon-General. He further presided in all matters concerning medical science—the examination of candidates for offices in the medical department of the army and in the military hospitals. The Surgeon-General had the appointment of all the surgeons of his department, and, as the exigencies of the service required, the discretion of placing those who were disposable in the hospitals, camps, and military districts. On the Inspector of Hospitals devolved the appointment and promotion of the apothecaries, purveyors, and their deputies, assistants, nurses, and servants for the hospital; the direction of the transport of medical supplies to the army and hospitals; and, lastly, in conjunction with the Surgeon-General, the examination of the claims of military officers for wounds and loss of limb.

As may easily be believed, from this separation of the service and patronage into three branches, made wholly independent of each other, though in reality they were, by the very nature of things, mutually dependent, there arose many serious inconveniences. The Surgeon-General was debarred of all right to present either the physicians of the army, or the inspectors, the purveyors, apothecaries, or hospital assistants to promotion. Yet was he held responsible for the functions of all these officers, since he had the disposal of them in the different posts of service.

The Inspector-General of Hospitals, again, selected on his own responsibility for the service of those hospitals the surgeons and assistant-surgeons who were nominated and promoted on the recommendation of another authority. The system was ingeniously contrived to bring about conflicts of authority and to cause intra-departmental jealousies.

By a regulation enacted in 1798 regimental surgeons were made at once medical officers, contractors and managers of expenditure—an arrangement that would seem to have been designed to offer at once the greatest possible temptation to corruption and the amplest facilities for succumbing thereto. "It would, however," says Sir James MacGrigor, "be difficult to believe, so powerful in the learned professions is the sentiment of honour in their calling, that even at that time when the subordinate class of medical officers was not always composed of men of the high standard of a later period, advantage was taken of such opportunities of malversation."

Abuses there were, however, and in 1808 a Military Inquiry was instituted into the administration of the Medical Board. This inquiry, which lasted four years, brought to light the hardly surprising fact that the expenditure on the medical service of the army had been profuse. The result was a pedantically rigorous economy in trifles whereby, in the words of Sir James MacGrigor, "the higher professional interests and those of science were almost wholly sacrified to pence."

History repeats itself in the medical affairs of the army as in other things. At the end of the last century, as at present, every improvement in the position and pay of the medical officers was wrung from an unwilling War Office by the brute force of circumstances. Soon after the beginning of the revolutionary war with France the greatest difficulty was found in getting properly qualified men for the service. It was at one time found absolutely necessary to advertise for them; and in fact, as Sir James MacGrigor puts it, to beat up for them by offering present pay and good quarters. Placards were posted on the college gates of Dublin, Edinburgh, and Glasgow, offering commissions to such as could pass some kind of examination, which, if passed, immediately entitled them, under a warrant of the Army Medical Board, to pay and quarters. They had, moreover, all their travelling charges defrayed from the place whence they came. This was continued for many years—indeed, till near the close of the war, and it was the occasion of many uneducated and unqualified persons being introduced to the service, not a few of whom, in quarters where the promotion was rapid, found means to pass through different grades to the rank of regimental and staff-surgeon. A good many apothecaries, and even druggists' apprentices, found their way into the service in this manner.

So impressed was Sir James MacGrigor by these evils, which he says he had witnessed hundreds of times, that when he became head of the Army Medical Department in 1815 his first object was to find a remedy for them. He gradually collected exact information as to the education and services of every medical officer in the army, and when in full possession of the facts he intimated to everyone who was deficient that he was not to expect any further promotion in the service until he had completed his medical education according to a scale which the Director-General, in conjunction with his colleagues at the Board, had established. At the end of the war there was a great reduction of medical officers, and a very large number were placed on the half-pay list. These Sir James MacGrigor recommended to betake themselves to colleges and schools of medicine, either at home or abroad. Accordingly a great number proceeded to Edinburgh, Glasgow, Dublin, Paris, and the German schools. Several went to these schools to perfect their studies, and to pass the time till they should be recalled to full pay, it being intimated to all that, the higher the qualifications any individual possessed, the better chance he would have of promotion. Further, not a few of the officers on full pay, at home or abroad, obtained six or twelve months' leave of absence, and proceeded to some of the schools to add to their qualifications. The effect of this measure, says Sir James MacGrigor, exceeded the most sanguine expectations he had formed of it. There appeared a new spirit of emulation in the service, which gained for officers of the department much credit with their brethren in civil life: while the effect of the measure in the advantage gained to the public service was incalculable.

The Surgeons of the Peninsular War.

Sir James MacGrigor's *Autobiography* enables us to form a tolerably vivid picture of the army surgeon of the beginning of the century. His own career was almost from the beginning one of marked success and distinction. After studying at Aberdeen and Edinburgh, he purchased a commission as medical officer, and was gazetted to the 88th, or Connaught Rangers, in 1793. In the following year he went with his regiment to Holland, where, he says, "the want of system in our hospitals and the inexperience of medical officers in the duties in which in after-years they became so expert were at this time very striking." He afterwards accompanied his regiment to the West Indies, to India, to Egypt, and to Walcheren. He then served as Chief of the Medical Department in the Peninsula under Wellington, whose confidence he won to a degree unusual with that inexpansive chief, who called him familiarly "Mac." So great was his influence, that he prevailed on Wellington to mention

medical officers in despatches, a thing which had never been done before. This was after the capture of Badajoz. The story is best told in MacGrigor's own words:

"I immediately made my way to Lord Wellington, and found him in his tent writing the despatches. He received me most cordially, and after I had given him my detail, thanked me much. He was in excellent spirits; I therefore said: 'I trust, my lord, you are satisfied that the medical officers during last night did their duty, as well as the military officers, and that you will receive my testimony that they discharged their arduous and laborious duties most zealously, and often under circumstances of personal danger of which they were regardless.' He replied that 'he himself had witnessed it.' I then added: 'Nothing could more gratify those officers, nothing could be a greater incentive to their exertions on future occasions, than his noticing them in his public despatches.' He asked, 'Is that usual?' My reply was: 'It would be of the most essential service,' and I ventured to add that 'really their extraordinary exertions gave them in justice a claim to this.' He rejoined, 'I have finished my despatch; but, very well, I will add something about the doctors.'

"When the gazette appeared, the medical officers of the army in England saw with delight that the merits of their brethren had been publicly acknowledged, in the same manner as those of the military officers. This was the *first time* that their merits had been thus publicly acknowledged; and the example of Lord Wellington has been followed after every great action that has since been fought, and some time afterwards the navy followed the example."

In the retreat to Portugal the extreme displeasure of Wellington was loudly expressed against more than one quarter. He at one time went so far as to say: "The medical department is the only one which will obey orders; on them I can rely for doing their duty." After the passage of the bridge of Salamanca, MacGrigor was disabled by the kick of a horse. No cart or other vehicle could be found to carry him off the field, and it seemed as if he must fall into the hands of the enemy. Wellington, hearing of his situation, instantly ordered his carriage—the only one in the army—to take him up, and in the course of the day the General called to inquire about him.

As a proof of the respect in which Sir James MacGrigor was held by military officers of all ranks, the following story, which is only one example of many of like nature that might be told, may be related. Long after the Peninsular war a medical practitioner paid a professional visit to a major who was suffering from a severe affection of the chest, to which he had been subject periodically since his lungs had been severely wounded by a musket ball at the storming of Badajoz. The officer, after giving particulars of his case, and explaining the nature of the injury which was the cause of his sufferings, suddenly inquired, "How is Sir James MacGrigor?" On being informed that he was tolerably well, the patient exclaimed, "We of the old times worshipped that man!" The last words, says the writer who tells story in the *Lancet* of October 12th, 1850, were uttered in a faltering tone, and followed by a flow of tears; when the nerve and firmness of the veteran returned, he added, "I love him! I love him!" The man must have had no common qualities who could make so lasting an impression on a lad of 16, for the officer in question was only of that age when the services for which he felt a lifelong gratitude were rendered him by Sir James MacGrigor.

The Iron Duke, who was not lavish of praise, wrote of MacGrigor in 1814: "I consider Mr. MacGrigor one of the most able, industrious, and successful public servants I have ever met with."

How splendidly the medical officers did their duty in the Peninsula appears from the following striking testimony:

"It was said with much truth by an eminent individual that he thought the extraordinary exertions of the medical officers of the army might be said to have decided the day at Vittoria, for their exertions had undoubtedly added a full division in strength to Lord Wellington's army."

The war was the means of developing operative skill of a high order among the surgeons. Speaking of the battle of Toulouse, MacGrigor says that many operations were performed after that bloody engagement, and he adds: "Great experience and reflection had at this time created among us a body of operators such as never were excelled, if ever before equalled, in the British Army."

Graphic pictures of the Peninsular surgeons are also given in *A Prisoner of France*, the memoirs of Captain Charles Boothby, of the Royal Engineers, from which extracts were given in the BRITISH MEDICAL JOURNAL of December 23rd, 1899. The delightful Dr. Maurice Quill, of *Charles O'Malley*, may also be taken as one type of the men who healed the wounds of Wellington's soldiers. Charles Lever, himself a member of the medical profession, had known many of the Peninsular veterans, and his sketch of the genial doctor whose "fine feathers" stirred the wrath of Wellington, was doubtless drawn from life.

THE SURGEON OF THE GRANDE ARMÉE.

The greatest military surgeon at the close of the last and the beginning of the present century was, however, Dominique Jean Larrey, the famous Surgeon-in-Chief of the Grande Armée Larrey was not only a great organiser and administrator, but a brilliant operator. He was the first to perform amputation at the hip-joint for gunshot wound, and to him surgery owes the oval method of amputation at the shoulder.

Few surgeons can have had anything like Larrey's experience in amputation. He was an ardent advocate of immediate amputation for gunshot wound, and he on one occasion removed no fewer than 200 limbs in twenty-four hours. A striking testimony to his skill is the fact that of the primary amputations performed by him in the wars of Napoleon he saved three-fourths, and that at a time when antisepsis and anæsthesia were as yet undreamt of. Of his readiness of resource and his masterfulness in carrying out whatever he considered to be for the benefit of his patients many stories are told. On one occasion, when the supply of meat ran short and there was no nourishing food to be had for the wounded, Larrey "commandeered" the horses of some officers of a cavalry regiment to make soup for his patients. When complaint was made to Napoleon, he upheld his Chief Surgeon. In Egypt, Larrey fed his sick on camel soup, which he pronounced to be superior in quality to horseflesh.

Napoleon in his later years often spoke of Larrey. Las Cases in his *Memorial of Saint Helena* reports the Emperor as speaking to the following effect on October 23rd, 1816:

"What a man, what a brave and worthy man is Larrey! What care was given by him to the army in Egypt and everywhere! I have conceived for him the highest esteem. If the army were to raise a column to the memory of any one, it should be to that of Larrey. He has left in my mind the idea of a truly honest man. He is truly a worthy man, for to science he unites all the virtue of an effective philanthropist. All the wounded are of his family. The chief object of his consideration has been to exert himself in his hospital, in which he has been so successful as to entitle him to both my esteem and my gratitude." Not long afterwards Napoleon made his will, and wrote in it: "I bequeath to the Surgeon-in-Chief of the French army Larrey, 100,000 francs. He is the most virtuous man I have ever known."

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE

(1) Nervous Complications of Diabetes Mellitus.

DESBONNETS has collected the various symptoms of diabetes as manifested by the nervous system (*Thèse de Paris*, 1900), and which he divides into motor, trophic, sensory, and mental. Under the first head muscular feebleness has long been recognised. It appears sometimes suddenly in the midst of apparent perfect health, affecting chiefly the lower extremities. It disappears with the reduction of sugar. Paralysis of various forms may occur—namely, monoplegia, hemiplegia, and paraplegia. Monoplegias do not seem to be common. They may affect the whole of the limb or a group of muscles. The majority of cases of paraplegia are in reality due to lesions of the peripheral nerves coming on very insidiously, many of the symptoms being worse at night. In some cases the lesion is temporary, while in others it remains. This form of paralysis may also affect the upper as well as the lower limbs, and bears considerable resemblance to alcoholic paralysis, there being marked foot drop, accompanied by wasting and reaction of degeneration. There is loss of the muscular sense, gait is uncertain, and Romberg's symptom is not uncommon. Cases exhibiting these symptoms therefore strongly resemble tabes, and as there may be anæsthesia, gastric crises, perforating ulcer, etc., the diagnosis may not be clear at first sight. Sensory manifestations of diabetes consist in various severe forms of neuralgia, affecting especially the sciatic, the trifacial, the intercostal, and cervico-occipital nerves. These may coexist or alternate, and are not infrequently bilateral, a fact which is of assistance in diagnosis. The pain is intensely severe, and may be very rebellious to treatment. There is generally an underlying neuritis. Gastralgia and arthralgia and angina pectoris are further manifestations met with in cases of diabetes. Even the special senses may be affected: thus, taste and smell may be lost or perverted; deafness is also met with. Eye symptoms have been recognised for a long time, and of these cataract is the most frequent, but amblyopia and ocular paralysis also occur. Bouchard believes that cataract is most frequent in albuminuric diabetes. Amblyopia occurs in two forms, the temporary and the permanent; the latter is progressive. Under the head of trophic lesions perforating ulcer was due to diabetes in 14 out of 91 cases collected. Muscular atrophy, loss of the nails and hair, inflammation of the nailbed are other forms. Mental symptoms vary. There may be profound depression with delusions. Narcolepsy and mania are recognised, while coma of the characteristic kind is of course the commonest. The writer considers that these nervous manifestations of diabetes have not much prognostic significance, as they may appear in so many different degrees in different patients.

(2) Examination of the Blood: Its Value to the General Practitioner.

AT the recent meeting of the American Medical Association, M. Howard Fussell read a paper on this subject in the Section of Practice of Medicine. He said that in some cases the blood examination is as important, and in other cases it is more important than the examination of the urine, and it is already acknowledged that an examination of the urine is necessary in every case. As a general practitioner the author examines the blood in all obscure cases. As a result of such an examination: (1) The physician will avoid administering iron to a patient because the face is pale; since all pale people are not anæmic. (2) It will be found that patients with flushed faces often have decided reduction of the hæmoglobin and of the number of red blood corpuscles. (3) Patients with cardiac and pulmonary symptoms are sometimes diagnosed as cases of organic disease, when a blood examination would reveal chlorosis. (4) Blood examination will positively indicate the presence or absence of malaria. (5) The diagnosis between leukæmia and other organic conditions, such as tuberculosis and carcinoma of the stomach, may be made. (6) The blood examination combined with the Widal test will diagnose between typhoid fever and malaria; or possibly, show a combination of the two diseases. (7) Counting the leucocytes will often give satisfactory results in clearing up obscure conditions. The physician does not need to take a microscope to the bedside of the patient; if the diluting tube is surrounded by a rubber band the blood may be preserved for a long time, and the counting may be done at leisure.

(3) Fæcal Vomiting and Antiperistalsis.

G. LANGMANN (*Festschrift A. Jacobi*, New York, 1900) describes the case of a young woman, aged 21, who was admitted to the German Hospital in New York in 1889 for vomiting and hæmatemesis. Four years previously the left leg had been apparently paralysed for nine months after an injury. Since that time severe pain along the spine was occasionally felt. During the two years before admission patient was said to have had attacks of peritonitis, vomiting, and hæmatemesis, and had habituated herself to hypodermics of morphine. In the hospital the patient sometimes vomited fæcaloid material, sometimes actual hard formed fæces. Scybala an inch thick were at one time thrown up. A fistulous communication between the stomach and colon was suspected, owing to repeated hæmatemesis and circumscribed pain in the gastric region. Indigo administered with an enema was ejected, together with fæces, from the mouth in less than fifteen minutes. An exploratory laparotomy was performed, but nothing abnormal could be discovered except a darning needle, which was impacted in the anterior wall of the stomach between serosa and mucosa. The wound healed well, and the vomiting ceased. About thirty-three days after the operation, however, nausea with vomiting of mucus and blood recommenced. Afterwards hard fæces were brought up again. About six weeks after the operation the stomach was washed out, and tepid water containing indigo was injected into the rectum. The patient was carefully watched, so that deception could be excluded, and yet nine minutes after the enema was administered she vomited a fæculent mixture of milk coagula with indigo. A week later some hard fæces wrapped in paper were found under the patient's pillow. The patient left the hospital soon afterwards, and was detected in some tricks at another hospital. She was then lost sight of. Langmann believes that the stercoraceous vomiting was genuine and spontaneous, and could not be brought on by will, and that only after perceiving on what point the medical interest centred did she try to imitate a symptom which had created so much sensation.

SURGERY.

(1) The Early Diagnosis of Laryngeal Cancer and its Treatment.

AT the meeting of the American Laryngological Association recently held in Washington (*Phil. Med. Journ.*, May 5th) a discussion on the early diagnosis and treatment of laryngeal cancer was introduced by John N. Mackenzie, of Johns Hopkins University, Baltimore. He said that leaving out of account the possible existence of a cancer bacillus, there remained three methods of diagnosis - namely: (1) The naked eye, or diagnosis by ocular examination; (2) thyrotomy; and (3) the microscope. The second, of course, was often included in and ancillary to the first. In his opinion it was impossible to exaggerate the importance of examination by the naked eye. It was the most practical of the three methods, and it was unfortunate that it was so often relegated to a subordinate position. Every resource of clinical work should be made use of before recourse was had to the microscope. It, indeed, should be the very last court of appeal. The literature of the day showed that far too little reliance was placed on clinical work, and far too much on the microscope. There was no solitary sign by which they could detect cancer. They must group all the phenomena and form their diagnosis accordingly. But supposing they had weighed all the facts, and a reasonable doubt still existed, would they not then be justified in removing a portion of the growth for the purpose of subjecting it to microscopical examination? In spite of all the authorities to the contrary, he emphatically said "No." The reasons he had for

objecting so strongly to the removal of any part of the affected tissue were that it exposed the patient to autoinfection, stimulated the growth of the cancer if such it proved to be, and often led to misleading conclusions. It was not to forgotten that cancer was an infectious process. He believed that sooner or later its bacillus would be discovered, and that then the disease would cease to be treated surgically, the place of the knife being taken by an antitoxin. Meanwhile the cardinal fact that they had to face was that the surgical treatment of cancer had resulted in failure because the methods had not been sufficiently radical. They had not completely removed the disease. So long as they left the lymphatics to carry infection to other parts they were bound to fail, and after painful experiences he had come to the conclusion that the only hope of success lay in the total extirpation of the organ and also the lymphatics.

(5) Excision of Circumscribed Cancer of Stomach.

Herhold (*Deut. med. Woch.*, February 15th, 1900) repeats Schuchardt's assertion that the surgeon must expect to encounter gastric cancer in three forms—first, as an essentially ulcerating variety with surrounding infiltration; secondly, as an infiltrating variety where there is little ulceration but widespread stiffening of the walls of the stomach, which at the same time shrink at certain points; and lastly, as a true tumour, well-localised and sessile or even pedunculated. Schuchardt finds that the first variety is worse than the first, owing to speedy infection of lymphatics beyond the limits of the stomach, whilst the third is the least malignant and certainly the best for operation and for good after-results. Herhold reports the case of a very cachectic man who consulted him in April last year, giving the usual history of great pain after eating and frequent vomiting. A hard movable tumour of the size of a hen's egg lay somewhat to the right of the middle line, three fingers' breadth below the ribs. Two months later Herhold found it lying to the left of the middle line; the patient admitted that it was very movable. Great and constant local pain with extreme emaciation set in, and the patient implored that an operation be undertaken. On July 29th, after the stomach had been washed out, Herhold made an incision in the middle line at the epigastrium. He found an exceedingly small stomach completely contracted around a tumour of the size of a man's fist. On opening the organ the tumour was found to be attached by a broad base to the middle of the anterior wall. The tumour was excised together with about one-fifth of an inch of the gastric parietes immediately surrounding it. The wound in the stomach was closed with a continuous suture, including the serous coat, and made firmer by several interrupted sutures. Then the abdominal wound was closed. Nutrient enemata were given for a week; no rise of temperature occurred. On November 25th, just four months after the operation, the patient had gained 40 lbs. in weight, and was able to cut wood and perform other manual labour.

(6) Branchial Epithelioma of the Neck.

Vean (*Rev. de Chir.*, March, 1900) describes a special variety of cervical tumour which is characterised: (1) From an etiological point of view, by its appearance at an adult stage of life, and almost exclusively in males; (2) clinically, by intense malignity; (3) anatomically, by its epithelial structure, its situation on one side of the neck, its close contact with the large cervical vessels, and its adherence to the internal jugular vein. The starting point of this growth serves to afford it a special place amongst tumours of the neck. It is not developed at the expense of any of the normal organs of this region, and by most of those who have studied its pathogeny it is regarded as a morbid outgrowth of remnants of the branchial apparatus. Branchial epithelioma, which is not by any means a rare disease, and has been carefully studied by many pathologists, is a deep-seated, firm, and rapidly-growing tumour, situated on one side of the neck, and making its first appearance below the angle of the jaw and above the level of the upper margin of the thyroid cartilage. The growth is, as a rule, freely movable from side to side. It is almost always adherent to the main vascular trunks of the neck, more especially the internal jugular vein, often involves the sterno-mastoid muscle, and only when fully developed and of large size attacks and produces ulceration of the skin. The chief, and often the sole functional symptom is severe pain. Operative interference with the growth is usually found dangerous and difficult, and total removal is often followed by recurrence in the course of one or two months. The chief source of danger in the operation for removal is the almost constant adhesion of the growth to the internal jugular vein. After a careful study of the relative pathogeny of these growths and other forms of malignant growth in the neck, the author arrives at the conclusion that the tumours here described as branchial epitheliomata are developed at the expense of fœtal residues included within the normal structures after obliteration of the branchial clefts. As one of the chief points in favour of this view, the author states that in observations by Cuneo and himself on the evolution of the branchial arches the production and transformation of epithelial *débris* around the internal jugular vein were distinctly proved.

(7) The Surgery of Tuberculous Kidney.

König (*Deut. med. Woch.*, February 15th, 1900) discusses tubercle of the kidney at great length, both as to its pathology and surgery. He distinguishes two forms, tubercle confined to the glandular substance and renal tuberculosis with pyelitis. Diagnosis of the first variety is rarely possible, whilst tuberculous pyelitis can often be distinguished, even when the bacillus tuberculosis cannot be found. On the other hand, clinical symptoms are not always typical, even in undoubted tuberculous pyelitis. Nor is it invariably possible to make sure that the opposite kidney is healthy. Nephrotomy and cystotomy are not the right operations for tuberculous kidney except in rare cases; the only reasonable course is extirpation of the diseased organ. That operation must often be undertaken when it is not possible to make sure beforehand that the pyelitis is tuberculous or the opposite kidney healthy. König goes further, and declares that it will prolong life and make existence tolerable in many cases where the bladder, prostate, and testis, or even the other kidney, are clearly tuberculous.

(8) Blepharitis and Scabies.

Scabies of the palbebral fissure is not a commonly-recognised condition. Raehlmann, however, describes this form of scabies (*Journ. de Méd.*, February 10th, 1900). The acarus seems to affect the ciliary follicles and may thus escape detection. There is considerable blepharitis, accompanied by itching and tingling, along the free border of the eyelids. The eyelashes fall out. There is hyperæmia of the inner marginal zone and of the neighbouring skin. A honey-like secretion covers the border of the eyelids and adheres specially to the point of emergence of the eyelids. There is often a considerable degree of conjunctivitis. The treatment recommended by Raehlmann consists in applying an ointment of Peruvian balsam 2 parts, lanoline 6 parts; or Peruvian balsam 2 parts, lanoline 4 parts, oil of sweet almonds 2 parts. This must be applied every day, and left on for about half an hour. The condition may be cured in four or five days, but the applications ought to be continued for some time.

MIDWIFERY AND DISEASES OF WOMEN.

(9) Uterine Fibroids and Heart Disease.

Chavannaz (*Rev. Mens. de Gyn. Obstét. et Péd.*, March, 1900) in describing a case of fibroid in a woman aged 37, states that she had been subject for eight years to intermenstrual pain; dysmennorrhœa had been present from puberty. At the end of seven years Fieux, of Bordeaux, discovered an interstitial fibroid as big as two fists, sharply bent on the cervix. The os externum barely admitted a surgeon's probe. The patient refused operation, but asked for relief from the dysmenorrhœa. Stomatoplasty was performed and a stem retained. The pains soon returned; nine months after the minor operation panhysterectomy was performed. The pulse was distinctly intermittent, the intermissions occurring several times in a minute. At the operation strong adhesions between the lower bowel and the tumour had to be separated. Owing to alarming symptoms the chloroform was discontinued before the pelvic floor was sutured; the gap between the broad ligaments was

drained. The patient was seen and examined five months later. She was in perfect health; a few attacks of a feeling of deep depression had come on at night, but these were due, in Chavannaz's opinion, to the removal of both ovaries. The pulse had become absolutely regular. He refers to a similar case recently reported by Cauchois, where an irregular pulse became regular after hysterectomy. It was implied in Chavannaz's report, and in the discussion, that the cardiac lesion was organic, but its nature did not transpire.

(10) Panhysterectomy for Cancer of Pregnant Uterus.

LUDWIG (*Centralbl. f. Gynäk.*, No. 14, 1900) operated on a woman aged 40 in the sixth month of her seventh pregnancy. The cervix was in great part destroyed by malignant ulceration, hæmorrhage had been severe, pain slight, and emaciation absent. The uterus was totally extirpated through an abdominal incision. There was some difficulty owing to the right parametrium being invaded by the new growth. At first there was high temperature and a small abscess developed in the parietes, when the pus escaped; afterwards recovery was rapid. Ludwig found an intact ovum in the uterus, but first removed the liquor amnii with a trocar in order to analyse its contents as compared with the contents of the same fluid at term. He found of solid matter 15.5 parts to 1,000 (average at term 10.7 to 16, Kaltenbach), of albumen 5.19 (average at term 1.8, Schröder), of urea 0.53 (average at term 0.16 in hydramnios 0.48, Prochownik, but Fehling detected as much as 4 parts of urea to 1,000 in the tenth month). The high proportion of albumen was noteworthy.

(11) Decidnoma Malignum: Pulmonary Symptoms.

PEHAM (*Centralbl. f. Gynäk.*, No. 14, 1900) removed a uterus from a woman aged 25. In March, 1899, she aborted; free hæmorrhages followed, and continued till the operation on October 9th, 1899. At that date the uterus was bulky, anteflexed, and quite movable. The cervix admitted the forefinger, which could reach a raw area as big as a half-crown towards the left cornu. A piece of the diseased tissue was excised, and the appearances of chorionic epithelioma detected; on that account the uterus was removed. Severe flooding set in on November 4th, just within a month after the operation; it was traced to a metastatic deposit on the anterior vaginal wall. A few days later hæmoptysis occurred, and since then there has been free expectoration of blood-stained sputum, in which no tumour substance could be detected. The physical signs indicated metastasis. In the substance of the uterine tumour (which was a vascular mass 1¾ inch in diameter) both syncytial cells and groups of the cells of Langhans's layer were detected. The vaginal metastases showed the same elements. Marchand found the two types of cell in pulmonary deposits in a similar case.

(12) Pessaries and Uterine Cancer.

MORESTIN (*Bull. et Mém. de la Soc. Anat. de Paris*, March, 1900) reports an instructive case of a patient who underwent a great deal of gynæcological treatment within ten years. When 34 a cystic tumour of the right ovary was removed. She recovered, a hernia developed in the cicatrix, and troublesome bearing-down pains set in. The uterus became slightly prolapsed. A red-rubber ring pessary was introduced, and gave relief, but the patient seemed to neglect all precautions as to cleanliness, and the instrument was not removed for years. For a few months she was troubled with a free sanious vaginal discharge. Morestin found a firm bleeding mass, shaped like the clapper of a bell, in the vagina. This mass was a hypertrophied, cancerous posterior lip of the cervix. It fitted in the aperture of the pessary, which was covered with old deposit. The uterus was the seat of myoma. It was removed by vaginal hysterectomy; *morcellement* was practised. The patient recovered from the operation. The cancer and the myoma were coincidences no doubt; but the prolonged local irritation caused by the pessary may have been the cause of the malignant disease, and certainly aggravated it when it had developed.

THERAPEUTICS.

(13) Monomethyl-xanthine.

ALBANESE (*Arch. Ital. de Biol.*, Tome xxxii, Fasc. 3, 1899) has obtained monomethyl-xanthine from the urine of dogs, excreted during the administration of caffeine, in sufficient quantities to study its physiological action. It occurs normally in dogs' and human urine, but in very small quantities, 1,000 litres of human urine containing only 1 gram. It is closely allied to theobromine and caffeine, as the following formulæ will show: Xanthine $C_5H_4N_4O_2$, monomethyl-xanthine $C_5H_3(CH_3)N_4O_2$, theobromine $C_5H_2(CH_3)_2N_4O_2$, caffeine $C_5H(CH_3)_3N_4O_2$. Extracted from the urine of caffeinised dogs it occurs as brilliant crystalline needles, which are insoluble in ether, almost insoluble in cold absolute alcohol, slightly soluble in cold water, easily soluble in hot. It is readily soluble in solutions of ammonia and other alkalies. It furnishes a hydrochlorate, which rapidly decomposes in water. In its physiological action, as would be expected from its chemical constitution, it occupies a position between the higher methylated xanthines and xanthine. In the frog, caffeine, the highest of the series, has two distinct actions—one on the spinal cord, through which, like strychnine, it produces true tetanic convulsions; the other on the muscles, which become rigid, as in rigor mortis, independently of the nervous system. Theobromine causes still greater muscular rigidity, but affects the spinal cord less than caffeine. In monomethyl-xanthine this difference is accentuated, so that while in rana esculenta a few tetanic contractions may take place, in rana temporaria there is only muscular rigidity. Xanthine itself produces muscular rigidity, but has no action on the spinal cord. In mammals, monomethyl-xanthine in large doses produces clonic and tonic convulsions, and arrests the respiration while the heart continues to beat. It has a much less powerful action on the heart than caffeine. Thus while caffeine in moderately large doses lowers the blood pressure, and causes irreguiarity of the pulse, a condition resembling the last stage, when digitalis is pressed, monomethyl-xanthine, even in very large doses, never produces cardiac irregularity, though the pulse-rate is increased and the blood pressure rises; in other words, large doses of monomethyl-xanthine produce the same effect on the circulation as small doses of caffeine. The most striking result of the administration of monomethyl-xanthine to rabbits is an abundant diuresis, the quantity of urine being often raised to more than ninety times the original amount. This diuresis is not observed in cats or dogs, and in this monomethyl-xanthine resembles caffeine and theobromine. The diuretic action of the series also accords with their chemical constitution. Thus caffeine is the feeblest diuretic, theobromine is more powerful, and monomethyl-xanthine more powerful still. No researches have been made as to the diuretic action of xanthine, but *a priori* it should be very energetic. The diuretic property of theobromine has already been utilised in practice. Combined with salicylate of sodium it forms the soluble "diuretin," which is superior to caffeine as a diuretic, and less dangerous, because the tetanic element is less marked. For the same reasons, and also because the fatal dose is much higher, monomethyl-xanthine should be preferred to theobromine, at any rate theoretically. Its disadvantages are its slight solubility and the method of preparation.

(14) The Feeding of Infants.

KELLER (*Centralbl. f. inn. Med.*, April 21st, 1900) opposes the old view that infants in the first year of life should be fed every two hours. Luckily very few mothers actually feed their children so often, unless they are ill. In the Breslau Children's Clinic no infant, whether healthy or diseased, receives more than five feeds in the twenty-four hours, the intervals between each being four to five hours. The results as regards nutrition are excellent, and the children soon become contented and used to the new regimen. Some experiments of Keller's showed that the absorption and retention of nitrogen and phosphorus, and therefore the assimilation of albumens, were uninfluenced by the length of the intervals, whether two or four hours, between the feeds. He interprets this to mean not that the length of the intervals is immaterial, but that rules for feeding infants should be made almost exclusively from clinical observation. In foundling hospitals and large institutions there is always more illness if the shorter intervals are the rule than when longer ones are adopted. Czerny found that neither the fact that the stomach was empty, nor that it was

possible to make the child suck were any indications for the giving of nourishment. The healthy stomach of a breast-fed infant is empty one and a half to two hours after a feed, but free HCl is not found till one and a quarter hour later. In an infant fed on cow's milk under physiological conditions three hours at least are required for the emptying of the stomach and two more for the appearance of free HCl. Czerny therefore fixes the minimum interval between the feeds at three hours for breast and four hours for bottle-babies. If the stomach is constantly overloaded the reaction, showing free HCl, and the motor function both decrease. In disease remnants are found in the stomach four or even five hours after a feed, and no free HCl can be detected. This proves that a certain time during which the stomach is empty is even more necessary for an ailing child than for a healthy, if the gastric motor and secretory functions are to be maintained. Although little importance is now attributed to gastric digestion, Pavlow's researches have proved that the excretion and composition of gastric juice influences the properties of all the other digestive excretions. It is therefore evident to what an extent digestion and assimilation are inhibited, when, two hours after a feed, fresh nourishment is introduced into the stomach of an ailing infant in which no free hydrochloric acid is present.

(15) Galvanism in the Treatment of Furunculosis.

Langmann (*N. Y. Med. Journ.*, June 2nd) has since 1881 treated furunculosis by the application of the galvanic current. His method is as follows: The cathode, exhibiting more intense reaction upon the tissue, is placed upon the furuncle; the anode somewhere in the neighbourhood, and a current of about 2 to 5 milliamperes is applied for from five to ten minutes. As a rule, one sitting daily is sufficient. The intensity of the current ought to vary both with the stage of development of the boil (the earlier stages being more sensitive), and with individual sensitiveness. Whoever has no galvanometer on his battery may regulate the current according to the sensations of the patient; the feeling of a lively sting, entering, as it were, the centre of the boil, just enough to be tolerated, indicates about the proper strength of the current. After having subjected to this treatment during these 19 years more than a hundred different cases of furunculosis, including all stages and types from a slight boil to an almost well-developed carbuncle, he feels entitled to say that all furuncles when treated in their incipiency dry up (abort). When a yellow pustule has formed around the central hair this little mass of pus is extruded, but no suppuration follows. Even when fluctuation is present the core is soon thrust out, pus escapes through the central hole, but the suppuration is insignificant, and the whole swelling quickly disappears, with or without antiseptic dressing. Whenever there is extensive suppuration he places a flat pledget of cotton soaked in 1-1,000 sublimate solution between the sponge and the skin. Whether this powerful antiseptic has a beneficial effect by cataphoric action or not he leaves undecided; those who have great confidence in cataphoresis may use it on all boils. Under such treatment some boils disappear after one or two applications, others require as many as eight; on the average four or five sittings terminate their existence. He did not have the chance during these years to encounter a regular malignant carbuncle, but he would not hesitate to treat it in the same way. Large furuncles with five or six pustules have yielded to the treatment as well as smaller ones. A well-known fact of the cathode is evident directly after its application—namely, the anæsthetisation. Patients, without being questioned, volunteer the assertion that they feel much easier around their boil, and this effect seems not to be transient; it lasts for a long time, perhaps a whole day. Whether faradisation may bring on the same or a similar result as the galvanic current he is unable to say. The electrolytic action of the induced current is decidedly weaker; its extended application, however, may have the same effect as that of galvanism. The minor satellites of the principal boil were either covered with the same electrode or left to themselves. They always aborted, and he has never seen a relapse within the following months.

(16) Artificial Carbonic Acid Baths.

Pajor (*Pester med-chir. Presse*, December 17th, 1899) recommends a simple apparatus, manufactured by Wagner and Co., Vienna and Buda-Pesth, for the preparation of carbonic acid bath. CO_2 is liquefied and stored in metal cylinders under pressure. Cold water under a pressure of one atmosphere is conducted by a pipe into an iron cylinder where the stream is divided into a fine spray. Into this cylinder the liquid CO_2 is also conducted and combines so intimately with the small particles of water that in a bath at 90·5° F. every litre contains about 2,000 c.cm. of CO_2, which agrees closely with the amount present in the strongest natural springs containing CO_2. Sufficient hot water is added to the bath to raise it to 90·5° F. while the cold carbonic acid containing water is flowing in. The pressure in ordinary supply pipes is usually sufficient for the cold spray, but if it is not a pressure of one atmosphere is obtained by pumping or from a cistern 10 metres above the bath. A carbonic acid bath thus prepared has great advantages over one prepared with bicarbonate of sodium and hydrochloric or sulphuric acids. The CO_2 is evenly distributed, and the quantity present is maintained uniformly until the end of the bath, just as when natural carbonic acid spring water is used. There is also no danger of damaging the skin, as is the case when acids are added to the water after the patient has entered the bath. For excitable or extremely neurasthenic patients or for cardiac cases weaker baths may be obtained by introducing the liquid CO_2 into the cylinder at a less pressure, for instance, half an atmosphere.

PATHOLOGY.

(17) Proteus Vulgaris and the Serum Reaction.

Rodella (*Centralbl. f. Bakt.*, May 4th, 1900) has conducted an experimental investigation on this subject. The animals were inoculated subcutaneously and intraperitoneally with ½ to 1 c.cm. of a two days' old culture in broth, or of sterile broth to which a portion of a two days' old agar culture had been added. For studying agglutination a 14 to 24 hours' old agar culture mixed with broth was used; the blood was obtained from the ear of the inoculated animals. With a 1 in 60 dilution a positive result was usually obtained in a quarter of an hour, with a 1 in 5,000 to 10,000 dilution in an hour and a quarter to two hours. The results are summarised as follows: (1) Power of agglutination was produced by injection of virulent cultures, or of the filtrate, or of cultures killed by heat. (2) This was also conferred by repeated feeding of guinea-pigs with cultures. (3) The blood of newborn guinea-pigs was agglutinative in two cases where the mothers had been inoculated 20 and 39 days before birth with a virulent culture. In one case where the mother was inoculated 10 days before birth the result was negative. (4) The milk of guinea-pigs whose young gave a positive result was also agglutinative. (5) The agglutination of proteus in the experiments described is specific.

(18) Mixed Infection in Pulmonary Tuberculosis.

Sata (*Beiträge zur pathol. Anat., Supplm.*, No. 3) has published the results of the examination of 21 cases of phthisis with reference to the question of mixed infection. The bacteria which in the course of the tuberculous process find their way into the lungs are first contained in the cavities, and then pass into the walls of the latter, and produce in association with the tubercle bacillus pneumonia, toxæmia, and septicæmia. Broncho-pneumonia results from the aspiration of the contents of the cavities into healthy lung tissue. Pneumonia is the principal result of mixed infection, and examination will show the secondary bacteria to be present in large numbers and in the walls and pneumonic surroundings of the cavities. Secondary broncho-pneumonia is in the first instance due to the tubercle bacillus, but the foci eventually contain other bacteria. The most advanced cases of phthisis are examples of mixed infection, and most of the pathological changes present are due to the latter. Clinically the condition can be deduced from the presence of fever. The most important bacteria in question are streptococcus pyogenes, staphylococcus pyogenes aureus, diplococcus pneumoniæ, pneumo-bacillus and its varieties, and a pseudo-diphtheria bacillus pulmonaris often found by Sata.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE

(19) The Prognosis in Diabetes.

F. HIRSCHFELD (*Berl. klin. Woch.*, June 18th and 25th, 1900) has collected the views of the chief modern writers upon this subject, and supplements them by the results of his own experience. All agree that the variability of the functional disorder in diabetes is so great that the prognosis in the milder form is considerably more favourable than has hitherto been held to be the case. According to the author, a relative cure—urine free from sugar on a diet containing 200 grams of carbohydrate a day—is to be anticipated if at the onset of the disease 80 to 85 per cent. of the carbohydrate consumed is completely burnt up in the body. He has observed the carbohydrate assimilation to retrogress after influenza, after attacks of colic (? pancreatic), and particularly on the supervention of boils or gangrene. He states that an increase in the glycosuria is often indicated by an increase in the amount of urine, while an improvement is accompanied by a decrease. Not infrequently a rapid increase in the body weight is associated with more glycosuria, which subsides upon stricter dieting. The cardiac weakness, which is a frequent complication, is favourably influenced by an antidiabetic diet—diminution of, if not complete abstention from, carbohydrates.

(20) Pulmonary Rheumatism.

RENDU describes a cases of what has been termed "pulmonary rheumatism" (*Journ. de Méd.*, May 10th). A young girl was admitted into hospital under his care with very marked pulmonary symptoms which closely simulated pneumonia in some respects. There is in such cases no initial rigor nor vomiting, while cough and expectoration are usually absent. There is, however, very intense dyspnœa, respiration being very rapid. There is considerable joint affection in the majority of these cases previous to the pulmonary symptoms, which latter come on as rapidly as does the arthritis. There seems to be on examination some superficial congestion of the lung without any evidence of pleural involvement. Breath sounds are somewhat harsh, and may even become tubular, but no *rales* appear. Percussion note is somewhat impaired. These signs may change from one part of the lung to another with considerable rapidity. In severe cases very grave conditions may show themselves in a short time ending with asphyxia. It is chiefly in the more severe cases of acute rheumatism that such pulmonary complications are observed. After a certain amount of resolution the symptoms may all return in the course of a few hours. The duration of these cases is as a rule from fifteen to twenty days, but occasionally may be prolonged from four to five weeks. The author does not find that salicylates are very advantageous; antipyrin seems to have a better effect from its sedative action on the nervous system. The drugs that are most strongly recommended are opium and digitalis combined. The former seems to reduce the depressing dyspnœa, while the latter acts as a cardiac tonic. Their administration, however, ought not to be prolonged beyond two or three days. The writer strongly recommends dry cupping, and also states that bleeding is the surest and best way to reduce the intense dyspnœa and the rapid spread of the signs through the lungs.

(21) The Diazo-reaction as an Aid to Prognosis in Tuberculosis.

MICHAELIS (*Berl. klin. Woch.*, March 26th, 1900) finds that the diazo-reaction of Ehrlich is of value as a prognostic indication in cases of pulmonary tuberculosis, and that when the reaction is present it renders the prognosis grave. From a large number of observations made on phthisical patients he has found that in 167 cases of the disease 111 gave a positive diazo-reaction and 56 gave no reaction. Of the latter class 5 patients were cured, 44 improved, 5 were unchanged, and 3 died. In the group of cases which gave the diazo-reaction the mortality was greater and the improvement smaller. Thus of 111 patients 30 died, 13 were not improved, and 15 were improved, while none were cured.

(22) Ungual Striation.

TREVES (*Giorn. dell' Acad. de Med. di Torino*, April, 1900), after examining the nails of some 800 persons, mostly mental cases, finds clear evidence that in addition to the transverse striations found in the nails after illnesses, there is peculiarly abundant and regular transverse striation which may be observed after attacks of periodic mental trouble. It is in psychoses of the periodic type that this transverse striation is especially well marked.

(23) Family Periodic Paralysis.

PUTNAM records the following case (*Amer. Journ. of Med. Sci.*, February, 1900). A young man, aged 24, of good health and unusual muscular development, and having a rather nervous temperament, was first attacked, when he was 14 years of age, with a peculiar form of paralysis. The attacks generally occur on Sunday or Monday, at intervals; the onset is generally rapid, the patient going to bed in his usual health, and waking in the morning unable to move hand or foot, though premonitory signs may be present in the form of a slight tendency to toe drop. It was noticed, also, that he was inclined to irritability a day or so before the attack. In the severer seizures the paralysis is so complete that the patient can hardly move any of his muscles excepting those of the lips and eyes. He is unable to raise his head if it slips off the pillow; there is no alteration of sensation. In less severe attacks the limbs feel heavy and difficult to move. The attacks last from a few hours to two or three days, but it may be a week or so before the muscles completely recover their power. The disorder seems to begin distally, the dorsal flexion of the foot being the first to go. The patient himself is under the impression that any set of muscles recently subjected to severe effort are the first to manifest any weakness. The paralysis usually comes on during the night, and when the attack is at its height the movements of the limbs nearest the trunk were the most impaired. The knee-jerks are absent, and the abdominal and plantar reflexes cannot be obtained. There is no response in the larger muscles to faradism, but the interossei respond to strong currents. In the interval between attacks, electrical actions are normal the reflexes are present, in fact, no abnormality can be ascertained. The only predisposing factor seems to be taking an unusual heavy meal. Similar cases have been recorded by Taylor, Mitchell, and others, who describe cases of recurring paralysis, and often met with in several members of the same family. These writers are inclined to look upon this disease as due to an auto-intoxication acting in a somehat similar manner to curare; in fact, the resemblance is very strong between the two conditions. Reference is also made to the analogies between periodic palsy and migraine.

SURGERY.

(24) Auto-infection in Cases of Hydatid Cysts.

A QUESTION of some interest with regard to the clinical history of hydatid cysts has recently been discussed at the Société de Chirurgie de Paris (*Bull. et Mém.*, Nos. 9, 10, 11, 1900). Peyrot, in communicating a case of extensive multiple development of hydatids in the omentum and the walls of the pelvic cavity following a rupture of a large hydatid cyst of the liver, expressed the opinion that this was an instance of invasion of the peritoneum by hydatids resulting from rupture of the primary and hepatic cyst. As a necessary condition of such infection the effused fluid, it was held, must contain scolices. Potherat, in the course of the discussion on this paper, opposed this view, which he regarded as a zoological heresy. A hydatid cyst, this surgeon asserts, cannot either by its fluid, its daughter cysts, or its scolices, reproduce a cyst of a like kind, such cyst being an intermediate stage in the evolution of the tænia echinococcus. When in the same subject there exist either in the same organ or in different viscera, or on the surface of a serous lining, multiple hydatid cysts, then, according to Potherat, these multiple cysts are to be regarded as diffused manifestations of a single or repeated invasions of the embryos, and not as inoculations of the contents of the primary cyst. Potherat's statement, however, was generally controverted by

subsequent speakers, amongst whom were Quénu, Broca, and Tuffier, and strong clinical evidence was given in favour of the view that daughter vesicles from a ruptured hydatid cyst may become engrafted in other structures, and by subsequent growth may form secondary hydatid growths.

(25) Meckel's Diverticulum; Fatal Obstruction.

Schmidt (*Deut. Zeit. f. Chir.*, vol. liv., December, 1899) in a valuable monograph on Meckel's diverticulum and ileus, relates a new case. A girl, aged 15, had been subject in infancy to discharge from the navel. When 6 an attack of obstruction occurred. For four weeks, when seen by Schmidt, a worse attack had been in progress. A lumbricus was discharged through the umbilicus, and the vomit was fæcal. The obstruction was incomplete, and irregular in severity; the patient was reduced to a skeleton. Schmidt operated, extirpating the umbilicus; then he discovered a diverticulum as thick as a lead pencil and quite viable. It ran into intestine, a half loop as it were; the other part of the loop could not be found, and the half loop was quite empty, yet surrounded with greatly dilated intestine. Several adherent loops were exposed; in a gentle attempt to separate them the intestinal wall was torn, and fæces escaped. The rent was sewn up and the wound closed; the diverticulum had been ligatured. The patient died within twenty-four hours. At the necropsy it was, as in many such cases, impossible to define the nature of the obstruction with accuracy; so the lower part of the ileum, cæcum, and ascending colon were taken away and dissected at leisure. The vermiform appendix was found to coil round an almost empty loop of intestine posteriorly. The lower half of the loop was the end of the ileum entering the cæcum. The upper half included the point on the ileum where the diverticulum entered. Three inches and a half higher up the loop ended at a point where the ileum was sharply kinked, chiefly by the end of the vermiform appendix, which adhered to it posteriorly and internally. The ileum, held against the umbilicus by its diverticulum, had become sharply coiled between the diverticulum and the colon; this had caused adhesive peritonitis and obstruction at the root of the coil. The adhesion of the vermiform appendix was no doubt secondary, and not the cause of the kinking of the gut. The hole made by the operator's fingers lay in the dilated intestine immediately above the obstruction.

(26) Treatment of Complicated Fracture of the Neck of the Humerus.

Farquhar Curtis (*Annals of Surgery*, March, 1900) reports three cases of fracture of the neck of the humerus with dislocation of the upper fragment, treated by operation. Careful consideration, based on his own and previously recorded cases of the relative merits of reduction, has led the author to the following conclusions: (1) In fracture of the upper end of the humerus with displacement of the upper fragment from the glenoid cavity, when proper attempts at simple reduction under general anæsthesia have failed, operative measures should be resorted to unless shock, other injuries, or extensive damage to the soft parts about the shoulder justify delay; (2) anterior displacements require an anterior incision, subglenoid or posterior displacements require a posterior incision, probably by Kocher's method; (3) the head of the humerus should, if it be possible, be restored to its place, and resection should be resorted to only when reduction is impossible or likely to cause such extensive damage to the parts, or such prolongation of the operation, as to increase the risks of wound infection or of shock; (4) resection will probably give a better result in fracture of the anatomical than in that of the surgical neck of the humerus, but reduction is to be preferred in both cases; (5) asepsis is an indispensable requirement for a good functional result, and operative interference in this class of injuries should not be undertaken except under aseptic conditions; (6) motion should be begun in the joint as soon as the wound has healed—in ten to fourteen days after the operation.

(27) Treatment of Unreduced Dislocation of the Elbow.

Loison (*Rev. d' Orthopédie*, No. 2, 1900) reports two cases of old unreduced dislocation of the elbow, in which he removed the lower end of the humerus. In his comments on these cases, the author states that in instances of long-standing displacement of the bones after backward dislocation of the ulna and radius at the elbow, no treatment short of osseous resection can have any good results. Passive movement, massage, subcutaneous section of fibrous adhesions, and even arthrotomy will usually fail in consequence of the development of ossifying periarthritis and the formation of osteophytes both in connection with the bones of the joints and as detached bodies in the surrounding muscles. The author holds that in such cases partial resection is indicated, and he agrees with Ollier that the best course to pursue is to remove the lower extremity of the humerus, and to leave intact the upper extremity of the ulna with the olecranon, and so to preserve the attachments of the biceps and brachialis anticus muscles. This operation, it is pointed out, is attended with some difficulty by reason of the irregularity of the displaced bones, and of the presence of osteophytic growths. The method of resection practised in the author's cases was that of a single cortical incision on the posterior surface of the limb carried through the triceps tendon and the median line of the olecranon.

(28) Umbilical Hernia: Operation on Newborn Child.

Kessel (New York *Med. Record*, March 3rd, 1900) adds a case to the two already recorded by Coley (*Ibid.*, November 4th, 1899; both cases operated upon about twenty-four hours after birth, both survived operation). In Kessel's patient the coils of intestine and liver could be seen clearly through the transparent membranes of the cord. Apparently all the abdominal viscera were in the tumour, which was as large as the child's head. The contents could be easily reduced. The umbilical ring was at once cut through, and the raw edges united with silk. The infant died during the night. Kessel concludes that death was due to the pressure of the reduced viscera in the abdominal cavity, which was too small to hold them. He observed, before operating, that every time that he reduced the hernia the pulse weakened, and grew strong directly he relaxed the pressure.

MIDWIFERY AND DISEASES OF WOMEN.

(23) Puerperal Gangrene of Uterus.

Beckmann (*Zeits. f. Geb. u. Gynäk.*, vol. xlii, 1900) insists that the so-called "metritis dissecans" should be given the name which really explains it—"puerperal gangrene of the uterus." It is much more frequent than is suspected by living authorities, and, owing to the perfection of antiseptic and aseptic treatment in public lying-in establishments it is commoner in private practice where such treatment is not so easy to carry out. Beckmann declares that diagnosis is easy, though our teachers say the contrary. The uterus enlarges from the beginning, and involution is completely checked. The discharge is characteristic, and so is the temperature range. Prognosis depends much upon the degree of infection, and complications of which the most essentially fatal is perforation of the uterine wall. The mortality is 27.5 per cent. Uncomplicated cases usually recover. Restoration of uterine function depends much upon the amount of necrosis of tissue before the advance of the disease is checked. The endometrium is rarely regenerated, and if so, it is renewed from relics deep in the uterine wall. Puerperal gangrene is due to streptococcus infection. The germs run deeply and widely along the blood vessels and lymphatics and cause extensive thrombosis. It is this pathological change which causes the gangrene of uterine tissue. The gangrene in fatal cases proceeds unlimited, in milder cases demarcation occurs, and suppuration along the limiting line causes the expulsion of the sloughy tissue. Beckmann notes that in no less than 52 per cent. of all the cases which he has collected some obstetric operative measure had been undertaken before the complication occurred. Lingering labour is frequently associated with puerperal gangrene. Enteric fever certainly predisposes to it. In the parts of the uterine wall which escape necrosis Beckmann detected vacuolation of the muscle cells. As to treatment he emphatically states that intrauterine injections are contraindicated.

(30) Calcium Carbide in Inoperable Carcinoma of the Uterus.

GRUSDEW of St. Petersburg (*Münch. med. Woch.*, June 12th, 1900) has employed calcium carbide in a number of cases of inoperable uterine cancer. Guinard was the first to introduce the treatment and to recognise that the effect is produced by the disinfectant action of acetylene and the caustic action of the lime, which are produced when calcium carbide comes in contact with water, according to the formula, $CaC_2 + H_2O = C_2H_2 + CaO$. The patient is placed in the lithotomy position, the vulva and vagina are disinfected, the cervix is exposed with a Simon's or Cusco's speculum, and the vaginal walls and the surface of the tumour are dried with cotton wool. One or two fragments of calcium carbide are then placed on the surface of the tumour by means of dry forceps, and are kept in place by a tampon, which is so arranged as to protect as much as possible the healthy parts of the vagina from the caustic action of the lime. The fragments of carbide are selected so as to correspond in shape to the surface of the growth, a pointed conical piece for a crateriform ulceration, and a plate-shaped piece for a superficial ulcer. The patient can then go about her work. In one to three days' time the tampon is removed, and a douche of carbolic acid or perchloride of mercury is given to remove any necrotic masses of growth and fragments of lime. According to the condition of the ulcerated surface the procedure may be repeated at once, or not until the symptoms (hæmorrhage, etc.) recur. The calcium carbide may also be applied in powder form through a vulcanite insufflator. After a single application all ragged, easily bleeding excrescences are destroyed, and there remains a clean wound, which generally does not bleed, or bleeds very slightly, and gives rise to very little secretion. Hæmorrhage, the most dangerous symptom of advanced carcinoma, is always arrested, however obstinate or of long standing it may have been. During the actual treatment the fœtid discharge generally increases, but soon after the removal of the tampon it diminishes and loses its intolerable odour. In many cases the pain is alleviated or removed, though this anæsthetic action of the carbide is not always obtained. After a week or perhaps longer the symptoms gradually return and the treatment requires repetition. Though the results are less permanent than those obtained by operative measures, such as scraping the growth with a sharp spoon and cauterising it with the thermo-cautery or bromine, the simplicity of the procedure makes it unrivalled under certain conditions; for instance, in outpatient work, and in practice when assistance or instruments are unobtainable. In Grusdew's experience the treatment is devoid of danger and painless, though some French gynæcologists have reported cases where it was painful. In one case the acetylene is said to have been developed so suddenly that it exploded and blew the speculum out of the vagina; the patient fainted, but was otherwise unharmed. In other cases the acetylene has forced its way through the uterus and tubes into the peritoneal cavity and caused violent abdominal pain. These accidents can be avoided (1) by well drying the vagina so that the acetylene is not developed too suddenly, and (2) by not plugging so tightly as to prevent the escape of the gas *per vaginam*. The writer never observed diarrhœa or other symptom of general calcium carbide poisoning.

(31) Preventive Gynæcology.

R. R. SMITH (*Amer. Journ. Obst.*, xli, 632, May, 1900), summarises the various possibilities of preventive gynæcology under the five headings of care of the woman before marriage, during gestation and labour, and during the climacteric, prevention of gonorrhœa and syphilis, and prevention of carcinoma. With regard to the two last named: carcinoma is to be prevented by the repair of all tears of the cervix occurring about middle life, and gonorrhœa and syphilis by the diffusion of a knowledge of the risks run when a woman marries a man of loose habits. The care of the woman before marriage includes the making of a physical examination in all cases of persistent or severe pain at or between menstrual periods and of protracted amenorrhœa without constitutional cause, also when there is menorrhagia without evident cause. At puberty the girl ought to have explained to her by her mother the fundamental facts of her reproductive functions. Care in pregnancy of course includes the examination of the urine. In labour surgical cleanliness is a *sine qua non*: a judicious use of the forceps may be a most useful means of preventing future gynæcological mischief. Tears should be repaired. The woman should be examined three months after labour. Minor pelvic surgery is the conservative gynæcology of to-day; when this is recognised there will be less major or abdominal surgery.

(32) Amniotic Knot on the Umbilical Cord.

COUVELAIRE (*Bull. et Mém. Soc. Anat. de Paris*, 6 s., ii., 282, 1900) describes a remarkable case in which an amniotic band passed from one part of the membranes to the other and in its passage was twisted thrice round the umbilical cord and in addition formed a knot on it in the third twist. The pregnancy, which was normal, was the seventh that the mother had had, but the labour came on prematurely about three weeks before it was expected. The infant was a male, weighing 3,850 grams; no fœtal heart was heard during labour and the infant had the appearance of being recently dead; *post mortem* no naked-eye lesions could be found. The placenta was circular and to the naked eye normal, but the membranous sac was incomplete, only half of the placental border giving attachment to a large piece of membranes from which a thin cord-like structure passed to another piece of membranes. The thin cord-like structure was composed of amnion alone and was more that 23 cms. in length. It had the relation to the umbilical cord mentioned above; it surrounded it thrice and formed a knot on it. The umbilical cord was 51 cms. long, very thick and œdematous save at the constricted point, where it had a diameter of only 7 mms. Through the constriction in the umbilical vein thus produced water could be driven, but only with the use of much force.

THERAPEUTICS.

(33) The Bath Treatment of Typhoid Fever.

BÄUMLER (*Sonderabdr. aus deut. Archiv f. klin. Med.*) gives the results obtained in 1,019 cases of typhoid fever by the cold-bath treatment in the medical clinic of Freiburg-in-Breslau. The mortality, which was 9.32 per cent.—or, excluding cases which were moribund on admission, 7.9 per cent.—contrasts favourably with Sidney Phillips's estimate, made in 1898, that the average death-rate from typhoid fever was still 18 per cent. (BRITISH MEDICAL JOURNAL, vol. ii, pp. 1485 and 1492). Baths act not so much by lowering the temperature as by improving general nutrition through the circulation and nervous system. In a similar case it is rarely possible to lessen the temperature by more than a daily average of 0.7° F. Several factors, however, influence the circulation: the peripheral vessels contract; the difference between the arterial and venous blood pressure, on which depends the rate of flow in the vessels, is accentuated, and the heart is stimulated mechanically: at the same time the respirations become deeper. For any permanent benefit to be obtained it is essential that the baths should be repeated frequently, so that the flow of blood from the peripheral to the central parts and from the central to the peripheral continues uninterruptedly. It is an open question whether the bath treatment has any influence on the mortality from intestinal perforation, and on the mortality from hæmorrhage it has almost certainly none. Apart from intestinal lesions the greater number of deaths (27.3 per cent.) were due to pulmonary complications, though bronchial catarrh was certainly less common than in cases treated without baths. The reason for this is that, owing to the comparatively good general condition of the patient, descending tracheo-bronchitis from the inhalation of infected material from the upper air passages—and this is the commonest cause of bronchial catarrh in typhoid fever—is avoided. It is most important to give the patient a drink of water after every feed in order to remove any remnants of milk or other decomposable material. As a rule the heart stands repeated baths excellently, and they are not generally contraindicated in cases complicated by nervous tachycardia, or by a rapid pulse due to pulmonary changes (emphysema, fibrosis, or chronic bronchitis) even when accompanied by great cyanosis. The same is

true of cases complicated by anæmia and fatty degeneration of the heart, though naturally caution is necessary. Practically, then, the only contraindications are abdominal pain and collapse, and when peritonitis, perforation, or hæmorrhage are suspected. The actual technique used at Freiburg is as follows: Whenever the temperature in the axilla reaches 103° F., a bath at from 82.4° to 75.2° is given. The patient remains in it with his head resting on an air cushion until he begins to feel cold, generally from 8 to 10 minutes, the skin, especially over the extremities, being rubbed constantly. After the bath he is wrapped in a dry sheet and covered with blankets; a hot-water bottle is placed at the feet. Some wine is given before the bath, and immediately after it more wine and hot soup. If there is great mental dulness, delirium, or pulmonary catarrh with atelectasis or broncho-pneumonia, cold water at 50° to 59° F. is poured over the patient for a short time at the end of each bath. Whenever possible, one bath should be given during the night. If the first bath is well borne, and the patient's strength is maintained, the temperature of the baths is soon reduced to 68° F. The diet should be liquid, and not too much alcohol should be given; large quantities relax the arteries and have the same action as the typhoid toxins. When there is great cardiac weakness, camphor is very useful and ammonia may be tried. Antipyretic drugs are only harmful. The patient should be made to drink large quantities of fresh cold water all through the illness.

(34) The Medicinal Treatment of Heart Disease.

Franz Dorn (*Berliner Klinik*, June, 1900) calls attention to the fact that the modern treatment of cardiac disease is so largely physical and dietetic that the study of the appropriate drugs has fallen somewhat into the background. He details the remedies used in Mendelssohn's clinic and their particular indications. In palpitation from mere nervous excitability cold-water bandages or icebags are not always effectual; in such circumstances a combination of valerian with sodium bromide is recommended. Not infrequently actual valvular disease is complicated by this heightened excitability, which may act unfavourably upon compensation; for this the author also gives valerian with aqua laurocerasi, belladonna, or bitter almonds. In mild cases of valvular disease an infusion of the leaves of nerium oleandri may be used as a substitute for digitalis; it is claimed that this quiets the heart and diminishes the pulse frequency, while at the same time it is very well borne. It is particularly indicated in the early stages of compensatory failure; later on digitalis is indispensable, and is, according to Dorn, best given as Traube recommended—that is, with quinine. The latter appears to exert a favourable influence upon the subjective symptoms. Where, however, these—for example, paroxysmal dyspnœa—are not so easily kept under, narcotics should be used; the author strongly advocates a hypodermic injection of morphine in the evening to ensure a good night. Where the kidneys are affected sulphonal or trional must be substituted. In the special dyspnœa of aortic valvular disease, with its wearing cough, the author advocates the administration of heroin, or, if that is not satisfactory, codein. He treats dropsy by a diuretic mixture containing digitalis, strophanthus, citrate of caffein, acetate of potash, and liquorice; he has sometimes found diuretin of great value in combination with one or other of these drugs. In chronic myocarditis and fatty heart—most cases of which he believes to arise from alcoholic excess—Dorn advises regulation of the diet, rubbing with cold, and spirituous applications, and the administration of quinine and iron. Where these fail the tone can often be restored by the nerium infusion mentioned above.

(35) The Dilution of Milk for Infants.

Bonifas (*Prog. Méd.*, February 24th, 1900) protests against the dilution of cow's milk in bottle-fed infants, because (1) the dilution, *pari passu*, weakens the digestive functions; (2) the added water demands an increased water-absorption by the stomach, and thus leads to early fatigue of the organ, whilst at the same time it acts as an irritant to the gastric mucous membrane; (3) the increased volume of fluid necessary for adequate nutrition causes digestive disturbances, and leads to gastro-intestinal dilatation and flatulence. Admitting that the best infant's food is the mother's milk, the writer holds that cow's milk approaches the relative composition of human milk very nearly, whilst the dilution of cow's milk tends not to approximate, but to entirely alter, its likeness to "mother's milk." To take one of the cases cited: A child, healthy at birth, was fed upon milk diluted with half water. The appetite was soon lost, and when two weeks old there was vomiting and diarrhœa. The stomach was distended, skin pale and leathery, abdomen tense, and body wasting. When 2½ months old, treatment was commenced. Two-thirds milk, one-third water was given. After two to three days three-fourths milk, and after four to five days whole milk was ordered. A week afterwards the child became bright, contented, and slept well; there was no vomiting, and the fæces were quite normal. A month later the abdominal distension had almost disappeared. From the day of birth cow's milk should be given undiluted, and increased in proportionate quantities as the child ages. By this means the constant crying, frequent vomiting, diarrhœa and wasting will be considerably minimised.

PATHOLOGY.

(36) The Parasitic Origin of Eczema.

Torok (*Ann. de Derm. et de Syph.*, February, 1900) discusses this question. He considers that we are only concerned with common forms of eczema. The parasitic theory rests on the following facts: (1) Every cutaneous fissure or abrasion may be the starting point of an eczema; (2) the auto-inoculablity of acute and chronic eczema; (3) the transmissibility of eczema; (4) the presence of parasites in the discharges. The author points out that auto-inoculability is not a proof of parasitism, because it may occur in acute eczemas of artificial origin. With regard to the transmissibility of eczema the greatest caution is necessary in the explanation of facts. As an example of this Torok cites the case of an infant affected with eczema since birth, whose mother contracted vesicular eczema of the hands. The latter was, however, found to be caused by tobacco juice. The parasites which may be found in eczematous products are numerous, and include staphylococcus aureus, citreus, and albus; streptococcus pyogenes; bacillus subtilis, etc. The author urges that these parasites only modify the disease, and are not the origin of it. In conclusion, Torok says that there is no serious argument in favour of the parasitic origin of eczema.

(37) The Heart in Anæmia.

Wybauw (*Journ. Méd. de Brux.*, March 15th, 1900) has made some observations on the alterations in the size of the heart in anæmic subjects. He finds that dilatation is commonly met with, and sometimes, especially in chlorosis, elevation of the diaphragm displaces the heart upwards and an apparent dilatation is found. Anæmic dilatation is to be considered true idiopathic dilatation resulting from overstrain. None of the usual symptoms are present; gastralgia alone is complained of. The precordial dulness should therefore be examined in anæmia, especially where gastralgia is one of the symptoms. This form of dilatation may disappear early, may persist for some considerable time, or may even be permanent in certain cases. In the latter hypertrophy is probably superadded.

(38) Invasion of the Intestinal Wall by Anguillula Intestinalis.

Askanazy (*Centralbl f. Bakt.*, March 4th, 1900) describes a case in which this hæmatode was found in the stools. The patient had pain in defæcation and melæna. *Post mortem* the stomach, duodenum, and jejunum were the parts in which the parasites were most numerous. The animal bores its way into the mucous membrane, finds nourishment there, and deposits its eggs. The embryos, unlike young trichinæ, do not find their way into the circulation, but are discharged into the lumen of the gut, producing hæmorrhages in escaping. When first the parasite finds its way into the intestine wall it burrows in the submucosa, but in the reproducing stage it is surrounded by inflammatory material, and the affected wall has a nodular, uneven appearance. The patient in this case died from intercurrent disease.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

(39) Indicanuria.

REALE (*La Clin. Mod.*, An. v, p. 22), discussing the clinical significance of indicanuria, finds it difficult to believe it can be due to fæcal retention, as in these cases the fæces are hard and, like solid bodies, almost insoluble. Indicanuria probably indicates defective proteolysis, and is often found in conjunction with uroerythrinuria. If the uroerythrinuria is constant and unaccompanied by indicanuria, it probably indicates hepatic disease; but if indican is present, the hepatic trouble is more likely to be functional. Indican is not necessarily due to putrefactive changes in the intestine, but may result from the mere breaking up of albumen. Indicanuria may also be present from altered tissue change, and is a fairly constant symptom in arthritics.

(40) Muscle Tone and Tendon Reflexes.

J. MUSKENS (*Neurol. Centralbl.*, December 15th, 1899) enumerates the following facts and views in support of the existence of a true reflex muscle tonus: (1) That after section of the posterior spinal roots muscular hypotonia results; (2) that in cases of unilateral facial paralysis the face is drawn towards the sound side, but that this inequality disappears in profound sleep; (3) that the sphincter ani remains contracted in sleep or in moderate narcosis from chloroform, etc.; (4) that the external strabismus produced by section of the third and fourth cranial nerves could be abolished by direct stimulation of the frontal lobes of the cerebrum (Sherrington), indicating a relaxation of the tonus of the muscles innervated by the abducens nerve; (5) that curare diminishes muscular tonus by producing a block to the nerve currents entering the muscle; (6) that in tabes dorsalis hypotonia of the thigh muscles in front (quadriceps extensor) is found. Observations were also made by Muskens on 400 patients, of whom 75 were subjects of chronic nervous diseases and 20 of internal (visceral) troubles. Special attention was paid to muscular tonus (measured by a special tropometer), to the tendo Achillis reflex, the knee-jerk, the plantar reflex, and myototic irritability. Dividing patients into three classes—for example, those with normal muscular tonus, those with increased (hyper-) tonus, and those with diminished (hypo-) tonus, it was found that the vast majority of patients with hypotonus showed also diminished tendon reflexes, the exact proportion being 90 per cent. In the remaining 10 per cent. of hypotonic patients the tendon reflexes were increased. Of patients who were hypertonic, two-thirds showed increased knee-jerks. It appeared therefore that there is some relation between the degree of tonus and the activity of the tendon reflexes, although there are fairly numerous exceptions to this rule. On specially investigating a large number of patients subject to alteration of cutaneous and tendon reflexes it was found that while in some there were exaggerated tendon reflexes and normal or diminished skin reflexes, in an equal number there were contrary phenomena—for example, exaggerated skin reflexes and normal or diminished tendon reflexes. As a result of these studies Muskens further concludes that the tendon phenomena are not true reflexes, although he admits it is impossible to decide this absolutely, and that a more careful study of the mechanical irritability of muscles is needed.

(41) General Paralysis.

SÉRIEUX AND FARNARIER have made a long series of investigations (*Rev. de Méd.*, February) as to the etiology of general paralysis. The conclusions they come to are as follows: By far the most frequent cause is syphilis, their statistics showing 18 per cent of cases certain and probable, in 50 per cent. absolutely certain. This disease is the sole factor in 31 per cent., in other cases combined with alcohol or heredity. In some few cases syphilis occurred with cranial traumatism. There is neuropathic heredity in two-thirds of the cases, but the writers are of opinion that this figure is too low, and that more extensive observations will show a greater percentage, for in their opinion heredity is almost an essential. The incubation of the disease is from 14 to 15 years, 6 and 36 being their extreme figures. In this period, however, they include the invasion of the disease, that is to say, that period during which the symptoms are unmistakable but the patient is not fit to be certified. This period of invasion may extend over 2 or 3 years. The average age for patients to show general paralysis in such a degree as to require certifying is 40, and taking into account 15 years for incubation and invasion, it would mean that at 25 the patient began his general paralytic history. As to the influence of syphilis, the writers admit that other poisons such as lead and alcohol, and possibly autointoxication, are competent to cause this peculiar form of meningo-encephalitis, but that the number of such cases is small. Therefore the action of syphilis is not specific, but seems to be merely a malign influence acting in conjunction with some hereditary fault.

(42) Extraordinary Impulses towards Auto-Mutilation.

BERILLON reported at a recent meeting of the Société d'Hypnologie et de Psychologie (*Rev. Neurol.*, February, 1900) the case of a man, aged 31 years, who was the subject of impulses of a dangerous and determined character towards self-mutilation. One morning, shortly after rising, he was seized with an irresistible impulse, and struck his head with a hatchet so as to bleed copiously. On another occasion he attempted to tear out his right eyeball, and as this did not succeed he had recourse to a knife for the purpose, and, later, he extracted several of his teeth one by one with pincers. One day he seized hold of his genitals with both hands and pulled at them forcibly so as to tear them out; and at times he would thrust his hand into the interior of his throat, which he would pull and dig till it bled. He once put out his tongue, and, closing his teeth over it, struck himself a violent blow upwards on the lower jaw so as to cause the tongue to be bitten through. While he was in the act of performing these mutilations the patient experienced no suffering, and seemed to be gratified when he had succeeded in accomplishing what he desired. These attacks or crises were never accompanied by loss of consciousness, nor by foaming at the mouth, nor involuntary micturition. They were acts reproducing in reality the material of dreams during the night immediately preceding such acts. This patient was subjected to hypnotic treatment. On the morning of January 16th, 1900, he once more had ideas of auto-mutilation, but his hands having been paralysed by hypnotic suggestion, he was not able to give effect to his impulses for self-destruction. The patient had become an object of scandal and notoriety in his district, and was regarded with horror by his fellow citizens. M. Berillon expressed his hope that with a continuance of the treatment he is undergoing there were hopes of his ultimate definite cure.

SURGERY.

(43) The X Rays in Surgery.

THE *American Journal of Medical Sciences* for July contains the report of the Committee of the American Surgical Association on the medico-legal relations of the *x* rays. After reviewing the evidence available on the subject, the Committee came to the following conclusions: (1) The routine employment of the *x* ray in cases of fracture is not at present of sufficient definite advantage to justify the teaching that it should be used in every case. If the surgeon is in doubt as to his diagnosis he should make use of this, as of every other available means, to add to his knowledge of the case, but even then he should not forget the grave possibilities of misinterpretation. There is evidence that in competent hands plates may be made that will fail to reveal the presence of existing fractures, or will appear to show a fracture that does not exist. (2) In the regions of the base of the skull, the spine, the pelvis, and the hips, the *x*-ray results have not as yet been thoroughly satisfactory, although good skiagraphs have been made of lesions in the last three localities. On account of the rarity of such skiagraphs of these parts special caution should be observed, when they are affected, in basing upon *x*-ray testimony any important diagnosis or

line of treatment. (3) As to questions of deformity, skiagraphs alone, without expert surgical interpretation, are generally useless, and frequently misleading. The appearance of deformity may be produced in any normal bone, and existing deformity may be grossly exaggerated. (4) It is not possible to distinguish after recent fractures between cases in which perfectly satisfactory callus has formed and cases which will go on to non-union. Neither can fibrous union be distinguished from union by callus in which lime salts have not yet been deposited. There is abundant evidence to show that the use of the *x* ray in these cases should be regarded as merely the adjunct to other surgical methods, and that its testimony is especially fallible. (5) The evidence as to *x*-ray burns seems to show that in the majority of cases they are certainly and easily preventable. The essential cause is still a matter of dispute. It seems not unlikely, when the strange susceptibilities due to idiosyncrasy are remembered, that in a small number of cases it may make a given individual especially liable to this form of injury. (6) In the recognition of foreign bodies the skiagraph is of the very greatest value; in their localisation it has occasionally failed. The mistakes recorded in the former case should easily have been avoided; in the latter they are becoming less and less frequent, and by the employment of accurate mathematical methods can probably in time be eliminated. In the meanwhile, however, the surgeon who bases an important operation on the localisation of a foreign body buried in the tissues should remember the possibility of error that still exists. (7) It has not seemed worth while to attempt a review of the situation from the strictly legal standpoint. It would vary in different States and with different judges to interpret the law. The evidence shows, however, that in many places, and under many differing circumstances the skiagraph will undoubtedly be a factor in medico-legal cases. (8) The technicalities of its production, the manipulation of the apparatus, etc., are already in the hands of specialists, and with that subject also it has not seemed worth while to deal. But it is earnestly recommended that the surgeon should so familiarise himself with the appearance of skiagraphs, with their distortions, with the relative values of their shadows and outlines, as to be himself the judge of their teachings, and not depend upon the interpretation of others who may lack the wide experience with surgical injury and disease necessary for the correct reading of these pictures. These conclusions were unanimously adopted as expressing the views of the American Surgical Association.

(44) Closure of the Cleft Palate by Lingual Implantation.

Carl Beck contributes a preliminary report on this subject to the *New York Medical Journal*, June 30th, 1900. In a case of cleft palate in which the Langenbeck as well as the Davies-Colley operation failed to cover the immense congenital defect he recently implanted a portion of the tongue. The ease with which even extensive resection of the tongue is tolerated by carcinomatous patients induced him to form a lateral flap from the tongue, which, after being turned and reflected near the base, was united with the freshened edge of the cleft of the same side. The gaping wound margins of the side of the tongue were accurately united then, and the floor of the mouth and the lingual angle packed with iodoform gauze. During the after-treatment a mild solution of boric acid was sprayed through the nostrils every fifteen minutes. Liquid diet was given exclusively. After nine days the base of the flap was severed, and one week later the flap was united with the opposite margin of the cleft, according to the usual uranoplastic procedures.

(45) Gluten-Casein as an Aid to Intestinal Suture.

Katzenstein (*Deut. med. Woch.*, October 12th, 1899) has utilised Buchner's discovery that certain vegetable albumens produce chemiotaxis when applied to serous surfaces in his experiments on dogs. These show that gluten-casein, which is a proteid substance obtained from gum, produces firm adhesions when applied to the peritoneum. After dividing the small intestine transversely, and powdering the cut edges with gluten-casein, the writer joined them with ten to twelve sutures involving the peritoneal and muscular layers. In every case the wounds were found to be firmly united eight days to six weeks later, and to have contracted fairly extensive adhesions to other parts of the intestine and the omentum. The hydrostatic pressure which the junction would stand without giving way increased after the operation from day to day. Even in rabbits, in which successful suture of divided intestine is extremely difficult, the method gave equally good results. Some control experiments proved that the same number of sutures were insufficient to completely seal the intestine without the aid of gluten-casein. Since the cut surfaces of the intestine, however closely sutured, unite by the adhesion of the peritoneal surfaces, and give way only because adhesions do not form sufficiently rapidly and closely, it is possible that the artificial local peritonitis produced by gluten-casein may prove of value in operations on the intestines of man.

(46) The Treatment of Old Fractures of the Patella.

Alessandri (*Il Policlin.*, May 15th, 1900), in old fractures of the patella with considerable separation of the fragments, has used with success a modification of Ferraresi's operation. A median longitudinal incision is made over the knee, completely exposing the fragments and a considerable part of the quadriceps extensor. A portion (10 cm. × 2 cm. × 5 mm. thick) of this tendon is dissected out, the fibrous tissue between the fragments cut, and the fragments freed from all adhesions, refreshed at the edges, and brought together. Next, the portion of tendon dissected out is firmly fixed by suture to the upper margin of the superior fragment, and its lower end carried over the two fragments and well sutured to the patellar ligament below; additional sutures are inserted along the sides. The edges of the gap left in the quadriceps were brought together with sutures, and the limb fixed in a position of forced extension.

MIDWIFERY AND DISEASES OF WOMEN.

(47) Porro-Cæsarean Section for Labour impeded by Fibroid.

Lepage (*Ann. de Gynéc. et d'Obstét.*, February, 1900) operated last summer on a woman, aged 41, in labour at term for the second time, and suffering from severe flooding. The placenta was inserted in the inferior segment, and the uterus was the seat of fibroid disease. Over two years previously, at her first labour, great hæmorrhage occurred from placenta prævia. The cervix, deformed and displaced by the fibroid, was dilated with great difficulty, but the child was dead already. The mother nearly succumbed. At the second labour hæmorrhage set in with labour pains. Lepage at once determined to operate. The os, dilated to the size of a franc-piece, was displaced forward by a tumour, which occupied without blocking the posterior and upper part of the pelvic cavity. A "Porro" was determined upon beforehand, if a pedicle could be formed, as the patient was in danger and required a speedy operation, nor could the vagina be thoroughly disinfected. Hence total hysterectomy was not thought advisable. Directly the uterus was drawn out, a median incision was made, and a living male child 10 lbs. in weight, was extracted. It was very pale, but survived, and was in good health when six months old. There was not much difficulty in making a pedicle and fixing it in the wound. The patient made a good recovery. In this case the fibroid masses—there were two—could be pushed up above the brim, but the fœtus could not be reached by the finger during labour, nor would it have been possible to get the hands or forceps into the uterine cavity to extract the fœtus. Lepage insists that when the child is living it should be extracted through an incision in the uterus before that organ is amputated.

(48) Total Extirpation of Septic Uterus.

Zipperlen (*Inaug. Diss.*, Tübingen, 1899) has collected 74 cases, and adds 2 in Doederlein's practice. In the first there was retention of placental relics, and in the third week after labour the curette was twice employed. Malignant degeneration was suspected. Grave septic symptoms appeared. The uterus was extirpated through the vagina; convalescence was very slow. In the second there was also retained placenta. The labour was at the seventh month,

with transverse presentation and premature rupture of the membranes. Abdominal section was performed. A uterus bipartitus septus was removed; it was infested with multiple interstitial fibro-myomata. The right ovary was not removed; the patient recovered. Of the 74 cases already reported, more than half (38) died. Zipperlen prefers original hysterectomy. Panhysterectomy by abdominal section is only to be practised in complicated cases, such as the presence of a myoma, etc. The retro-peritoneal abdominal operation is, of course, quite out of the question when the uterus is septic.

(49) Intestino-vaginal Fistulæ.

CONDAMIN AND VORON (*Arch. Prov. de Chir.*, June, 1900) state that intestino-vaginal fistula is not infrequently observed after operation on the pelvic organs. Such fistula is sometimes the result of an abnormal communication between the intestinal canal and a purulent collection (inflamed dermoid cyst or suppurative annexitis), established before the date of surgical intervention, and in other instances was caused during the operation either by laceration of the intestine in breaking down adhesions, or by puncture with a trocar or wounding with a cutting instrument. The authors regard this lesion as by no means a serious one, and state that the fistulous communication nearly always heals spontaneously and in a short time. In the rare cases in which the fistula persists it may be closed either by cauterising the fistulous track or by laparotomy and intestinal suture. The benignity of intestino-vaginal fistula, if considered with regard to the equal frequency and the much greater gravity of stercoral fistula following laparotomy, constitutes, it is held, an important argument in favour of the vaginal method in the treatment of inflammation and suppuration of the pelvic organs.

(50) Double Vulvar Tumour.

A. O. LINDFORS (*Upsala läkareförenings Förhandl.*, N. F., Bd. v, p. 213, March, 1900) describes the case of a woman, 44 years of age, who for three or four years had suffered from a solid tumour of the right labium majus. Examination disclosed the fact that there was a second tumour cystic in nature on the other side in the left labium majus. Both were operated upon, and it was then found that the one on the right was a fibroma and the one on the left a cyst of Bartholin's gland. Lindfors remarks on the rarity of double tumours of the vulva. The uterus was retroverted and somewhat tender, and the ovaries were slightly prolapsed.

(51) Treatment of Uterine Fibroids.

EDWARD J. ILL (*Buffalo Med. Journ.*, lv, p. 751, May, 1900) stated at a recent meeting of the Buffalo Academy of Medicine that the mere presence of a uterine fibroid was not an indication for operation. The contraindications he grouped under seven heads: (1) When the patient was unaware of having a growth or any symptoms therefrom; (2) when she discovered the growth but suffered neither mentally or physically; (3) when the symptoms were of minor importance; (4) when she could nurse herself, suffered little, and could afford to be carefully watched; (5) when she had passed the monopause, having an old and likely a calcareous tumour causing few if any symptoms; (6) when she was near the menopause and could remain under observation until it was past; and (7) when she was suffering from other and more serious disease likely to lead to fatal results. The cases which were to be treated by operation were: (1) Those in which life was or might be endangered directly or indirectly by the growth, as with the bleeding or septic or twisted or inflamed myoma; (2) those in which health was so impaired that life became a burden, although not endangered, as from large or very movable or very painful tumours; and (3) those in which mentality suffered because of the presence of the tumour, as in sensitive unmarried women, women bordering on the melancholic, and women who thought all tumours must of necessity be cancerous.

THERAPEUTICS.

(52) The Electric Light in Rheumatic Affections.

MOUBINOFF (*Vratch*, No. 6, 1900) after experiencing in his own person the favourable effect of the electric light in acute rheumatism, began in 1897 a series of clinical experiments with that agent. In the majority of cases he used the electric arc of 20 to 25 ampères and 50 to 60 volts. The light was reflected by a parabolic mirror, and the action of the heat rays was sometimes suspended. Without committing himself to a definitive judgment as to the therapeutic effect of the electric light, the author provisionally formulates the following conclusions: (1) The temperature of the light of the electric arc (20 ampères) reflected by a parabolic mirror is in direct ratio to the distance. Thus at a distance of 125 cm. from the source of the light it is of 110° C., whilst at a distance of 4 metres it is only 24.2° C. (2) The light (with or without heat rays) acts not only on the superficial layers of the integuments, but on the deep-lying tissues. (3) The pencil of light having traversed a living tissue decomposes bromide of silver on a luminous plate. (4) The action on a luminous plate coated with gelatine bromide does not belong exclusively to the blue-violet rays of the spectrum but equally to the others. (5) The light pencil having traversed a living tissue acts on the gelatine bromide plate with greater rapidity and intensity the thinner the tissue and the more concentrated the rays. (6) The brilliancy of the light pencil (in its entirety, not the so-called chemical rays alone) after traversing a living tissue is considerably less than that of a pencil which is on the point of entering a tissue—a fact which is obviously due to the thickness and physical properties of the tissue. (7) To obtain the therapeutic effect the light pencil must be used in its entirety without exclusion of the heat rays where this is possible. (8) The light of the electric arc directed on a given portion of skin induces hyperæmia of an intensity proportional to the nearness and intensity of the source of the light; in some cases hyperæmia is produced even when the light rays have been suppressed. The hyperæmia is produced more rapidly and is more intense when the light falls on the skin perpendicularly than when the direction of the pencil is oblique. (9) Besides hyperæmia the light produces sweating at its point of action. When the temperature of the light rays is high the sweating is profuse, and if the action of the light is prolonged sweating often becomes general. (10) On whatever part of the body the pencil, with or without heat rays, is directed a modification in the pulse wave is noticed. (11) After some hours of application of the electric light general fatigue and drowsiness are observed in most cases; less frequently there is more or less pronounced excitement. (12) As regards the therapeutic action of the light a diminution, or even disappearance, of the pain is noticed from the first. This effect persists for a period varying from a few hours to two days. If the treatment is prolonged the pain permanently ceases. (13) Under the influence of the electric rays the articular exudations which are present in rheumatic affections and in serous affections of the pleuræ disappear. The same thing takes place in the œdema of gouty affections. Relapse, however, sometimes occurs. (14) The electric light has a certain influence in reducing temperature. The light of the electric arc (20 to 25 ampères and 50 to 60 volts) is sufficient to cure affections of rheumatic character and certain diseases of the skin. The author thinks that the electric light will unquestionably occupy an important place in the therapeutic arsenal. At present, however, it must be used with precaution, as it is not altogether free from danger.—A. G. Minime (*Ibid.*, March 11th, 23) reports several cases in which he employed a 16 candle-power incandescent light in the treatment of joint affections—such as acute articular rheumatism, acute synovitis, etc.—and also in hæmatomata, torticollis, and neuralgia. He uses a combination of massage and illumination of the part. Absorption of large hæmatomata was effected in three sittings. Small effusions of blood were absorbed after fifteen or twenty minutes' treatment. In a case of acute traumatic synovitis of the elbow, the effusion disappeared in seven sittings. Ivanoff has devised a special lamp which is a combination massage roller and electric lamp.

(53) The Action of the Heat Rays of Light.

DRIGALSKI (*Centralbl. f. Bakt.*, June 23rd, 1900) records some experiments on the bactericidal and therapeutic results obtained by the use of the incandescent electric light in the form of a "light

bath." It is to Finsen that we owe the suggestion of the value of light therapeutically employed, and the bactericidal action of the blue, violet, and ultra-violet rays. In contradistinction to sunlight and the electric arc light, the incandescent light has been used by Kellogg, Winternitz, and others, and accredited with some special and somewhat mysterious property. The action of the green and yellow rays has not been thoroughly investigated; Finsen has shown that the red rays act entirely as heat rays, and that it is the chemical rays—the violet—which restrain the growth of bacteria. The red rays, the chief constituents of the incandescent light, certainly produce very rapid and extensive perspiration, but Kattenbracker has found that animals infected with the tubercle and diphtheria bacilli show increased resistance when kept in a light bath of these rays as compared with animals similarly infected and kept in the dark. Drigalski has carried out experiments with anthrax, and has obtained exactly opposite results. The light used was an incandescent lamp of 15-candle power; it induced excessive perspiration and symptoms of exhaustion, and all the animals infected with anthrax and kept in this light bath died before those kept in the dark. He concludes that these rays are worse than useless therapeutically, and should be excluded in any light bath.

(54) Treatment of Rodent Ulcer by X Rays.

Stenbeck (*Hygeia*, Stockholm, 1900, p. 18) describes a case of rodent ulcer on the tip of the nose of a woman, aged 67, treated by the Roentgen rays. The rays were applied for ten minutes daily at a distance of 10 cm. Reaction occurred after four sittings, and on the tenth pus appeared. After thirty-five sittings the ulcer was more healthy, and the epidermis began to grow in from the edges. After a short interval the sittings were increased to fifteen minutes, and a second reaction took place followed by improvement. The epidermis grew over the ulcer, the edge flattened down, and in a month a smooth cicatrix was left, differing little from the facial epidermis, and surrounded by a slightly raised border.

(55) Hedonal.

Schüler (*Wien. klin. Woch.*, June 7th, 1900) publishes 21 cases in which this new hypnotic was used in Krafft-Ebing's clinic. Hedonal is methyl-propyl-carbinol-urethan, a white crystalline body which can be administered either dissolved in dilute spirit, or, if its rather persistent after-taste is objected to, in cachets. The dose is from 15 to 30 grains, given an hour-and-a-half after the evening meal; in successful cases natural sleep followed in from a quarter-of-an-hour to an hour and a-half. Its perfect harmlessness bears out Dreser's experiments on lower animals. In Schüler's series of patients hedonal was completely successful only in 9; in 5 it failed, while in the other 7 its action was doubtful. The author concludes that it is not to be regarded as a universal hypnotic but that it is very valuable in cases of mild insomnia where the capacity for rest and sleep is present, but its onset is hindered by cerebral irritability. It is free from the special disadvantages of chloral and paraldehyde and can be usefully given alternately with trional, even for a prolonged period.

(56) Exercise Treatment of Heart Disease.

Vaquez (*Gazz. degli Osped.*, June 12th) is not in favour of the Oertel method, but thinks that benefit may arise from the Schott-Nauheim treatment, the exercises being much more important than the baths. In so treating patients, it is most essential to begin slowly and gradually, for example, first with partial massage, then passive movement, and finally carefully supervised active movements. The chief contraindications are high arterial tension and albuminuria, with renal insufficiency. Contrary to the experience of most authors, Vaquez has found the Schott treatment useful in angina pectoris. Again, he differs from many writers in strongly condemning the bicycle as a means of exercise in heart disease. In tachycardia and other cardiac neuroses little benefit has followed the Schott treatment.

PATHOLOGY.

(57) The Bacteriology of Purulent Meningitis.

Scheib (*Wien. klin. Woch.*, No. 25, June 21st, 1900) records the bacteriological results he obtained in a case of purulent meningitis in a female child, 8 days old. Cultures were made both from the pus in the meningeal cavity and from microscopical sections of the meninges, which were in a state of advanced purulent inflammation. Micro-organisms were found presenting the following characteristic morphological features: they were short rods, usually constricted in the middle, and distinguished by their rounded ends. They measured on an average from 1.4 to 2 mm. in length and 0.5 m. in breadth. They usually occurred as single rods, more rarely in pairs, being as a rule situated in the interior of the cells, and easily accessible to the process of discoloration by Gram's method, and not motile. With reference to its identity, this micro-organism differs from the bacterium coli commune, for which it might be mistaken by its luxuriant growth upon all nutrient media and its entire immobility; further, by the fact that in solutions of milk sugar and grape sugar the organisms cause intense fermentative action, and that they yield no typical reaction when treated with indol. From the bacillus pneumoniæ (Fraenkel) again they differ by their great capacity for, and the rapidity with which they induce, fermentative processes, and also by the absence of any brown coloration in gelatine cultivations, so highly characteristic of the former. Cultures injected either subcutaneously (in large doses) or into the veins (in small doses) of mice, guinea-pigs, and rabbits, the animals, as a rule, died within a few hours of inoculation, or at latest after a period of from one to three days, death being preceded by violent diarrhœa and high elevation of temperature. On the strength of their biological and morphological characters, and particularly their great pathogenicity for mice, rabbits, and guinea-pigs, the author is inclined to identify this organism as the bacillus lactis aërogenes, which was first cultivated by Escherich, along with the bacterium coli commune, from the fæces of infants. Since Escherich's description this bacillus was found by other observers in connection with cystitis, pyelitis, and pyelonephritis, and is—at least by some bacteriologists—regarded as the actual morbid agent of the last-named affections.

(58) Micro-organisms in Ascarides.

Demateis (*Gazz. degli Osped.*, June 3rd, 1900) in view of the fact that ascarides may cause small punctiform wounds of the mucosa (already more or less irritated by their presence) and may under the stimulus of high temperature emigrate into surrounding tissues, carrying with them whatever germs they may have in or about them, has carefully analysed the contents of the intestine of a certain number of ascarides. In each case bacteria were found, some of which were pathogenic or liable to become so. The chief varieties found were: B. coli, acidi lactici, erythrogenes, subtilis, mesentericus vulgaris, fluorescens, and varieties of streptococcus, for example, S. cereus, pyogenes, liquefaciens, aureus, etc. It is obvious that organisms which carry about with them such microbic luggage as this may give rise to trouble wherever they deposit their burdens, for example, in the liver, causing abscesses.

(59) Lymphoma: Malignant or Innocent?

Le Count (*Journ. of Experimental Medicine*, vol. iv, Nos. 5 and 6), in an article on lymphoma resembling a lymph gland, describes at length the pathological features of a tumour of this kind. He begins by showing that the classification of tumours more or less made up of tissue resembling that which makes up normal lymphatic glands is at present unsatisfactory. Hence the prognosis of a tumour of this kind is very uncertain; most surgeons tend to consider that it is malignant. When such a growth disappears spontaneously it is generally held to be an enlarged lymphatic gland. Le Count's sample was neither a malignant tumour nor an enlarged gland. It developed in the left groin of an adult male, and attained the size of a pigeon's egg by a gradual growth extending over fifteen years. The inguinal canal was not patent, and there was no enlargemen of the adjacent glands nor of those of the opposite side. The patient was in good health; there were no similar tumours elsewhere in the body. The operation was performed three years ago and there has been no recurrence. The tumour was a non-inflammatory new growth of lymph nodes.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

"(60) Hysterical Fever."

KOBLER (*Wien. med. Woch.*, June 23rd, 1900) adds two curious cases to those recorded by Heubner and by Dippe. The first was that of a healthy baker, aged 21, who, while under treatment for an ulcer of the foot was suddenly attacked with convulsions and fever. He had opisthotonos, twitching of all the muscles, spasm of the eyelids, and repeated stoppages of respiration lasting from half to three quarters of a minute. There was almost total loss of consciousness. The temperature rose to nearly 108° in the axilla, but the pulse was 72, and quiet. These attacks lasted from three to ten minutes, and were repeated daily at about the same hour; they were accompanied by œsophageal spasm, completely preventing deglutition. The hysterical nature of the affection was shown by the fact that the attacks yielded equally well to enemata of chloral hydrate or plain water; they were ultimately cured by the threat of immersion in ice-cold water. The second patient was an 11-year-old boy, in whom during convalescence from an attack of enteritis there supervened each evening at 6 o'clock precisely sudden and intense pain in the ileo-cæcal region, lasting for three or four hours, during which period he had complete motor aphasia. The temperature rose meanwhile, at its highest touching 106°; the pain and aphasia disappeared as suddenly as they had come on. No abnormal physical signs were detected. The patient was cured in the same way as the former. The author discusses the probable pathology of these cases, and concludes that they seem to support the notion of a true "hysterical fever."

(61) Epilepsy Cured by an Attack of Hemiplegia.

D. BRUNET (*Arch. de Neurol.*, March, 1900) publishes the following case. Usually cerebral lesions which result in hemiplegia are followed by epileptiform troubles or by choreiform and athetoid disturbances; but the reverse—namely, the arrest (or cure?) of epileptic seizures by the occurrence of hemiplegia is novel. The case is that of a woman born in 1812, single, uneducated, an inmate of La Charité since March 1857. She was epileptic since the age of 7 years, the first convulsive attack following scarlet fever. The attacks took place once every month or fortnight, and were followed by delusions and visual hallucinations of men assailing or attempting to kill her. In 1857 she had an attack of incomplete left hemiplegia following violent convulsive attacks. Thereafter the fits which she used to suffer from gradually diminished in severity, and in 1860 she was entirely free from fits. There was complete freedom from fits for seventeen years till her death in 1877. During this time her intelligence was almost normal; she could walk and could use her hands in needlework, though the left leg and arm were rather weak, and her disposition and character were quiet and orderly. She only suffered from occasional lassitude or from headaches, her habits were clean, and she never wetted her bed as patients in asylums not uncommonly do. No explanation can be offered to account satisfactorily for the complete disappearance of her epileptic attacks. A necropsy was not obtained in this case, but it is believed that cerebral hæmorrhage was the immediate cause of the attack of hemiplegia.

(62) Contracture and Spasm in Facial Paralysis.

GHILARDUCCI (*Il Policlinico*, June 1st, 1900) reports 7 cases of facial paralysis (peripheral), upon which he founds the following theory as to the pathogenesis of contracture in these cases. He believes it to be due to a want of equilibrium in the opposing tonic forces of the facial muscles: for example, if the orbicularis palpebrarum acts whilst its opposing muscle, the frontalis, is paralysed, the palpebral fissure is lessened and the eyebrow drawn down. The associated spasms are explained as an exaggerated (owing to loss of control by the atrophied muscles) degree of what occurs in a mild degree physiologically, as one of the modes of emotive expression (compare Spencer's account of why we laugh or cry from emotion). The prognosis of the contracture depends on the greater or less degree of the paralysis and atrophy of the muscles opposing those which are contracted. This theory brings facial contracture after paralysis into line with the similar condition of things in infantile paralysis of the limbs.

(63) Permanent Non-Progressive Ataxia.

SANGER BROWN (*Amer. Journ. of Med. Sci.*, June, 1900) reports three cases of this affection. All commenced with an acute illness, probably infective in nature, and in two associated with severe headache. This was followed by profound general muscular ataxia, conspicuously affecting the muscles of articulation. The ataxia once established became stationary, and the general health and mental condition were thenceforth normal. In a case recorded by Dinkler, where the initial acute infection lasted only five days, marked improvement occurred in the ataxia, during a course of treatment extending over five years. Sanger Brown believes the disease to be due to a toxin affecting either the part of the cerebellum subserving the co-ordination of voluntary movements, or the neurones connecting this part with other regions of the nervous system. Its localisation and pathological nature are, however, still quite uncertain, and the speech condition is remarkably unlike that in any common nervous disease; the patient, with mental powers unimpaired, being reduced to a few guttural monosyllabic grunts, or at best an occasional isolated simple word, in which the dental and labial qualities are strikingly deficient.

SURGERY.

(64) The Muscular Affections of Gonorrhœa.

BRAQUEHAYE AND SERVEL lately contributed an article on the subject of gonorrhœal myositis, and Servel now publishes further observations (*Thèse de Bordeaux*, 1900), which go to show that lesions of the muscles are very much much more frequent in this disease than has been supposed. In a slight degree the muscular affection may constitute a merely myalgia, but in more severe forms actual inflammation is present constituting myositis. This is much more common among men than women, and the important cause seems to be some severe muscular effort. It may be several weeks after the infection, or by relapse to an acute condition in an old-standing case that the attention of the patient is drawn to some part by severe muscular pain. Three weeks is generally speaking the average period for such to appear. As a rule there is little else than pain, and physical examination of the part may reveal nothing, there being no redness, swelling, or œdema. In other cases the slightest touch may demonstrate considerable tenderness sufficient to make the patient cry out, and at the same time it may be noticed that the muscle contracts irritably. Sometimes the patient assumes various attitudes to obviate the severity of his suffering. The general condition is as a rule good, but in the more severe cases there may be some more temperature—that is to say, than in those properly called myositis. In these cases there may be marked swelling of the muscles, and palpation becomes intolerable. The swelling is hard, non-fluctuating, and merges insensibly with the mass of the muscle affected. This swelling is unconnected with the skin, and may be moved with the muscle. Even in severe cases œdema and glandular swelling are uncommon. Prognosis generally speaking is good, subsidence being the rule, whereas in other forms of myositis suppuration is not uncommon, and even should this not occur there is generally some alteration, fibroid or otherwise, of the muscle, none of which occur in the gonorrhœal form. The duration of the disease extends over some days, ten at the very utmost. The treatment consists in sedative applications and wrapping up the affected part. Hot douching is extremely good.

(65) The Radical Treatment of Varicocele.

NARUTH (*Wien. klin. Woch.*, January 25th, 1900) states that all his cases of varicocele were associated with considerable enlargement of the inguinal canal. In the belief that this is of some importance in the etiology of varicocele he has devised a new radical

operation. An incision about 4 inches long is made as in Bassini's radical cure of hernia, and the veins are resected within the inguinal canal, which is then closed by Bassini's method. The advantages are that the circulation in the spermatic veins is interrupted with greater certainty, and the spermatic artery is spared more surely than in any other method. The etiological factor of the enlarged inguinal canal is done away with and the testis is raised. At the same time the difficulties of sterilising the skin of the scrotum and of isolating the spermatic artery from the venous plexus are avoided.

(66) Radiography in Pulmonary Surgery. Tuffier (*Bull. et Mém. de la Soc. de Chir.*, March 6th) in the course of a discussion on the operative treatment of multiple bronchiectasic cavities, directed attention to the use of radiography in the diagnosis of this morbid condition. He believes that in many cases in which the diagnosis is doubtful, or the auscultatory signs do not give reliable results and fail to localise with precision the pulmonary cavity, the Roentgen rays will reveal them on the fluorescent screen. Interlobular collections inaccessible to the usual methods of examination may thus be diagnosed. In a case of gangrenous abscess of the superior lobe of the right lung, in which, as usually occurs in cases of this kind, the stethoscopic signs were negative, Tuffier, by the help of radiography, was enabled to discover and open the abscess. Instances of this kind, it is stated, might be multiplied. A radiographic examination will in most instances of multiple cavities reveal the presence of all, and so prevent the surgeon from acting under the impression that there is only a single cavity. Radioscopy, however, it is pointed out, is not an absolutely infallible means of diagnosis. In cases in which the existence of pulmonary cavities is rendered certain by auscultation the *x* rays may fail to give any result. This is not surprising, especially if the lesions be situated in the lower parts of the lungs near the abdominal organs and the heart, as the affected regions are then covered by organs which are too thick to be readily traversed by the rays. The radiographic picture does not present the exact limits of the pulmonary cavity, but only the extent of the surrounding zone of sclerosed tissue. Tuffier has much faith in the prospects of radiography in the surgery of the lungs, and believes that, with further improvement of apparatus, observers will be able to distinguish minute differences in the thickness of tissues, and so determine with precision the seat, the limits, and, probably, the nature of pulmonary lesions.

(67) Restoration of Movement after Nerve Section. Robert Kennedy (*Proc. Roy. Soc. Edin.*, 1899) points out that after union of a divided nerve the return of function may be, as is well known, not only a restoration of tracts or fibres for sensation and voluntary movement, but the re-establishment may be sufficiently precise and complete to allow of complete localisation of sensation and a complete co-ordination of movement. To investigate the point whether such perfect recovery of sensation and of movement was due to a majority of the fibres in the divided end being accurately adjusted *in situ* before suturing, three experiments were made on the sciatic nerves of dogs. In two experiments the peripheral cut end, before reunion by suture, was twisted to the extent of a semicircle, so as to bring a maximum number of non-corresponding fibre-ends into juxtaposition, while in the third experiment reunion was made as accurately in the normal position as possible. The following results were obtained: (*a*) In the case of the wrongly coapted nerve, the dog until the seventh day after the operation showed no sign of returning function, and when it walked the hind paw was dragged along the ground dorsal surface downwards. On the seventh day the plantar surface was for the first time correctly placed on the ground in walking. Frequently, while walking, the paw turned over and was rested on the dorsal surface, but the normal position was voluntarily regained after a step or two. "This was taken as evidence of returning co-ordinated movements." On the tenth day undoubted evidence of sensation was obtained; on the fourteenth day (the bandages being removed and the wound being found healed) the animal could use the paw correctly, "almost always placing the plantar surface of the paw on the ground correctly." On the fifty-fourth day the nerve was exposed by incision, and was found united in the position in which it had been sutured, and stimulation of the nerve "above, below, and on the seat of reunion gave the normal contractions in the muscles of the leg." (*b*) In the case of the second dog similar results were obtained as recovery of movements and of sensation, and examination of the nerve on the thirtieth day showed it to be united in the position in which it was sutured, and to have regained its normal irritability and conductivity. (*c*) In the third case the sutured ends being very accurately coapted *in statu quo ante*, the animal first showed signs of recovery of function on the seventh day, and on the following day it was able to voluntarily readjust the paw when it happened to place its dorsal surface on the ground. By the eleventh day evidence of sensation was obtained, and by the fourteenth day the recovery of function was complete. On the forty-ninth day "the physiological examination showed that reunion of the nerve had taken place both anatomically and physiologically." As regards recovery of function, therefore, these three experiments followed a practically identical course. Microscopical examination made at the site of union showed the cicatricial segments were all three practically identical in structure. The arrangement of the young fibres was very irregular and tortuous, the fibres showing in all directions and closely resembling the appearance of a neuroma. In no case could continuity of nerve fibres from the central to the peripheral segment be traced in a single section. It is hence doubtful whether the restoration of function was accompanied by a re-establishment of the old paths by decussation of fibres in the nerve cicatrix. The practical conclusion is that in suturing a divided nerve no trouble need be taken to secure coaptation precisely *in statu quo ante*, the simple approximation of the two ends being all that is required.

MIDWIFERY AND DISEASES OF WOMEN.

(68) Treatment of Gonorrhœa in Women. Gardner (*Montreal Med. Journ.*, April, 1900) gives the results of his experience as follows: In the acute stage the patient should be kept in bed. The diet should be simple, the bowels regulated by salines and warm hip baths, and frequent irrigation of the genitals employed. Irrigations of linseed tea are very soothing. After the acute stage douches of permanganate of potassium 1 in 5,000, perchloride of mercury 1 in 5,000 to 1 in 2,000, or formaldehyde 1 in 4,000 to 1 in 2,000 may be used. The perchloride must be used with caution, owing to the fact that a pool of the solution sometimes remains in the vagina, and this may be absorbed. The perchloride douche should, therefore, be followed by warm water. The douche should be given in the dorsal position on a bed pan. Douching should be followed by careful application of silver nitrate (20 to 60 grs. to the ounce) to the whole surface affected, through a sinus speculum. Protargol or argonin may be used instead. The urethra and Skene's tubules, the ducts of Bartholin's glands, and the cervical canal must be treated by application of the same remedies. The urethra and cervical canal may be treated by instillations, the Skene's tubules and Bartholin's ducts with a small, slender-nozzled syringe. In the intervals of the silver applications, a solution of 5 to 10 per cent. ichthyol-glycerine may be applied to the accessible affected areas by means of tampons. In the treatment of the uterine cavity, local treatment must be avoided in all but the advanced chronic stage, because instrumentation in the early stage is apt to lead to extension to the tubes and ovaries. In affection of the Fallopian tubes and ovaries the author advises time and patience. By long rest in bed, good nursing, and judicious symptomatic treatment, many cases get well, and a favourable pregnancy may follow. Moreover, if operation be inevitable, the longer the interval since the acute symptoms have subsided, the more favourable will be the result. The fact of the extreme rarity of general gonococcal infection of the peritoneum supports this view.

(69) Torsion of Hydrosalpinx. Hartmann (*Ann. de Gynéc. et d'Obstét.*, February, 1900) reports a case of

a woman, aged 33, who was seized with vomiting, abdominal pain, and distension after having been subject for nine years to pelvic inflammatory symptoms traced to gonorrhœa. She had been once pregnant, just ten years before the attack. She referred the pain to the right iliac fossa, but it soon radiated in all directions. After rest and the application of ice to the abdomen the symptoms abated, but there was much local pelvic pain. He exposed, on opening the abdomen, a mass of omentum, which strongly adhered to a round black structure adherent to all adjacent parts. On liberating the structure, it proved to be a hydrosalpinx with twisted pedicle; it seems to have revolved on its short axis as well, like the hand of a watch. The ovary, which, like the distended tube, lay on the left side, was not twisted. The pedicle of the tube was ligatured. The thread snapped; immediately the uterus swung round to the right; it had been twisted half a turn to the left, forwards, by the hydrosalpinx, which had swung in that direction and become adherent. The affected tube and ovary were really the right; on search the left were found almost healthy and therefore not removed, but the appendix adhered to the twisted tube. Its mesentery was tied, then the usual collar made, with excision of the mucous membrane, and the stump was sutured into the cæcum. The pelvis was drained. Recovery was rapid. Hartmann collects 15 cases of twisted inflamed tubes. The right tube seems to rotate to the left, like the hand of a watch in natural motion; when the left tube twists it moves to the right, like the hand of a watch when its owner is putting back the time.

(70) Dystocia: Teratoma of Fœtal Omentum.

PAQUY (*Comptes Rendus de la Soc. d'Obstét. de Paris*, May, 1900) publishes the report of a 7-para subject, towards the eighth month, to œdema of the abdominal walls and inferior extremities. There was no albuminuria, but the patient was placed on milk diet. Labour set in and in nine hours the waters burst, they were greenish and very free. The shoulder presented and the cord prolapsed. One foot was brought down. Then it was discovered that the fœtal abdomen was much distended and ascites was suspected. Traction was made on the breech, but without effect, the os was imperfectly dilated. Suddenly sharp pains set in and the child was delivered within ten and a half hours from the beginning of labour. It was a female and quite dead. The abdomen measured over 14 inches in circumference and through its walls a soft tuberous mass could be felt; at points there was obscure fluctuation. All the abdominal and pelvic organs were normal, except the omentum, which was occupied by a tumour made up largely of cartilage with glandular elements and abundant blood vessels. In fact it was a teratoma due to fœtal inclusion. They are always supraumbilical and closely connected with the digestive canal. Out of 28 cases collected by Répin their seat is noted in 14, namely, between the layers of the transverse mesocolon 5; between the kidney, pancreas, and diaphragm, that is to say, at the base of the transverse mesocolon, 1; in the folds of the mesentery, 5; between the layers of the great omentum, 2; in the gastro hepatic omentum, 1 case.

(71) Rapid Growth of Uterine Fibroid.

OLSHAUSEN (*Zeitschr. f. Geburtsh. u. Gynäk.*, vol. xliii, Part II, 1900) successfully removed a myoma of the uterus weighing 39 lbs. There was some trouble on account of great dilatation in the veins of the left broad ligament, but little blood was lost. The tumour tissue was firm as usual, free apparently from any mucoid degeneration. The patient was 50 years old. Olshausen found that she had been examined by a competent authority just ten years since, when she was 40, and the uterus appeared normal. When 42 a small uterine tumour was detected. When 44 she was first examined by Olshausen. He found that the uterus was of about the size it usually reaches at the sixth month of pregnancy. After that examination the fibroid steadily attained colossal proportions. There were no cysts in the tumour substance, but one lymphatic vessel on the surface was so big that at first the operator suspected that he had cut away part of the ureter.

THERAPEUTICS.

(72) A New Method of Toxin Treatment in Tuberculosis.

LANDMANN (*Hyg. Rundschau.*, Jahrg. x, 1900, No. 8) describes a preparation of tuberculous toxin which he has named "tuberculol." He considers that such a preparation should be (1) a true fluid and sterile; (2) capable of killing healthy guinea-pigs in small quantities; and (3) must contain all the specific and active elements of the bacillus culture in unaltered form as far as possible. It should also be suitable for subcutaneous injection, and thus used should immunise the animal and produce antitoxin in considerable quantity. He takes exception to Koch's tuberculin R. on the ground that it is only a suspension, that the dose is too large, and that some of the active elements of the culture are excluded by the long subjection to a temperature of 100° C. Neither Buchner's plasmin nor Behring's toxin fulfils the above-mentioned requirements. The author's preparation is obtained by extraction, first, at 40° C. by physiological salt solution, distilled water, and glycerine, and subsequently at higher temperatures, gradually reaching 100° C. The various extractives are mixed and kept *in vacuo* at 37° C. The final residue is wholly inert, showing that all the active elements of the bacilli have been removed in the extracted material. The preparation is subsequently filtered and standardised. Landmann succeeded by means of this tuberculol in conferring immunity on animals in a large number of experiments. Subsequently he administered it to patients, beginning with a very small dose and slowly increasing; he eventually gives much larger quantities than in Koch's method with tuberculin R. He avoids exciting any great reaction at first, and extends the injections over a period of about four months, increasing the intervals gradually for fear of any cumulative action of the toxin. He succeeds in conferring a degree of immunity which is retained over a long period, although it is not of high degree. Tuberculol is a clear, thin fluid, but is best kept in a dry form; it consists in this form of brown scales, easily soluble in water.

(73) The Influence of the New Food Substances on Intestinal Putrefaction.

CARL LEWIN (*Zeitschr. f. diätet. u. physikal. Therapie*, July, 1900) records the effects of a large number of new food preparations on the bacterial processes in the large intestine, as shown by investigation of the ethereal sulphates, fatty acids, phenol, and indican in the urine. The substances he employed were plasmon, tropon, nutrose, somatose, sanatogen, aleuronat, and eulactol. Their action was compared in the same subject with a normal diet, and in some cases with that of five times the amount of scraped meat (that is, 250 grams per diem against 50 grams of the artificial food) as well. The author finds that the casein preparations exhibit no advantages as regards intestinal putrefaction over those made from meat or vegetable proteid. Pure casein derivatives, such as plasmon and nutrose, evoke no less intestinal putrefaction than tropon or aleuronat, while nutrose causes more fatty acid to appear in the urine than any of the others. None of these bodies influences the process more than another, and they cannot be said to affect it either favourably or unfavourably to any appreciable extent. Of some therapeutic importance is the fact that the administration of pure albumen preparations during convalescence from scarlet fever led to no untoward consequence. The five fold quantity of scraped meat had no more effect on intestinal putrefaction than the proteid preparations. Hence Lewin concludes by agreeing with Leyden that the sole value of these foods is the concentrated way in which they provide nutriment.

(74) Roentgen Rays for the Removal of Hair.

W. A. PUSEY (*Journ. Cutan. and Genito-urin. Dis.*, xviii, p. 302, July, 1900) points out how the accidentally-discovered effects of the *x* rays upon the skin and its appendages have been utilised in the treatment of various cutaneous affections. These effects have been (1) epidermal, as seen in the pigmentation of the epidermis, in the blanching and outfall of the hairs, and in trophic changes in the nails; and (2) dermal, as seen in inflammatory changes in the corium and subcutaneous tissues. Schiff and Freund have succeeded in

removing undesirable hairs by this means, and Jutassy has reported 40 cases in which there had been no regrowth of the destroyed hairs; and the author has shown that with a very weak but definite current the hairs from an entire area can be successfully removed. The removal is attended by no disagreeable sensations and by no accompanying symptoms beyond at times a slight erythema or pigmentation lasting a short time. It is not nearly so tedious as electrolysis, and can be applied to the hairs of a large surface at one time, and it is particularly adapted to cases in which it is desired to remove down and profuse growth of hair. In mycotic diseases of the hair and hair follicles the first part of the treatment consists in epilation, and this can be done in an ideal way by the *x* rays; further, the rays may do yet more good by their bactericidal action, due either to their direct effect or to the increased phagocytosis which they set up.

(75) "Hetol" in Phthisis.

Ewald (*Berl. klin. Woch.*, May 21st, 1900) has employed intravenous injections of "hetol" (sodium cinnamate) in 25 cases of phthisis, selected to fulfil as far as possible those conditions which Landerer, who introduced the method, considers to give the best chance of success. Thus no large cavities were present; in 11 the entire course was apyretic, in 10 there were long apyretic intervals, and in 4 only was there continued pyrexia. The technique is simple and quite devoid of danger if thorough asepsis of the skin and syringe is secured. After causing a vein, which is generally the median, to become prominent by a bandage round the arm, the point of the needle is introduced through its walls, and the required amount is injected into the circulation. The 25 patients received 461 injections between them without a single mishap. One mg. ($\frac{1}{65}$ gr.) of a solution of hetol (the strength of which is not mentioned) is the initial dose. The injections are usually given every other day, and the dose is gradually increased up to 15 mg. (about $\frac{1}{4}$ gr.), which should not be exceeded. Hetol is said to act by causing active inflammation round, and eventual cicatrisation of, the tuberculous foci, and the process has been actually demonstrated experimentally in the rabbit. Eleven of Ewald's cases were under treatment for 80 or more days, that is far more than the average time required, according to Landerer, for the cure of slight cases. Amongst these one was treated for 316 days, another for 221 days, and several for 150 days or more. The other 14 cases were treated, with one exception, for 30 to 80 days. Only 3 cases showed an improvement more marked than any usually seen in the clinic with ordinary hygienic treatment. (1) A woman, aged 28, was admitted for hæmoptysis, with dulness and moist crepitations at both apices. After 5 hetol injections there was another slight attack of hæmoptysis. Six days later, as the condition had improved and the temperature was normal, the injections were resumed, 35 being given in 127 days. The crepitations gave place to harsh respiration, the tubercle bacilli disappeared from the sputum, and the weight increased 8 lbs. 13 ozs. (2) A man had dulness at both apices after acute pneumonia, with tubercle bacilli in the sputum. After 19 injections the dulness had disappeared, though there were some inspiratory crepitations in the right suprascapular fossa, there was no expectoration, and there was an increase in weight of 17 lbs. 10 ozs. (3) The third case improved remarkably for a time, but there was a relapse, and death occurred six months later. The necropsy showed that the tuberculous process was still active. A fourth patient died, apparently of phthisis, but *post mortem* the cause of death was found to be fatty degeneration of the right ventricle, the tuberculous process in the lungs having healed. He had been under treatment for 316 days and had received 70 injections. Altogether 14 cases improved, though 11 not more than could be accounted for by the ordinary hospital treatment, and 10 were unbenefited. Of these 7 died, though some had been treated for 120 to 221 days, and had had as many as 58 injections. These results contrast very unfavourably with the 51 to 85 per cent. of recoveries obtained by Landerer himself. The probable explanation of the difference is that the favourable climatic conditions of Landerer's sanatorium are more powerful factors in the recovery of his cases than the injections of hetol. Disadvantages of the treatment observed by Ewald are a tendency to hæmoptysis, and in many patients great weariness and somnolence. The bacilli show no degenerative changes, and the temperature and night sweats are uninfluenced. Nevertheless, since the injections are not dangerous, they deserve further trial (see also Epitome, vol. i, 1899, par. 237).

(76) Treatment of Boils.

Hutchins (*Atlanta Journ.*, April, 1900) recommends the employment of antiseptic poultices in the treatment of boils after incision. A flaxseed meal poultice is made with 3 per cent. carbolic lotion, and applied over a layer of gauze. The poultices should be changed frequently. By this means continuous drainage by absorption in the poultice is obtained, and all pus and necrotic tissue come away. The carbolic acid prevents reinfection, and the warmth and moisture of the poultice are said to prevent premature union of the edges.

PATHOLOGY.

(77) Pathology of Plague.

Zabolotony (*Arch. des Scien. Biolog.*, T. viii, No. 1) has had the opportunity of studying plague in Bombay, in Arabia, and in the district of Weytcharg in Mongolia, where it has been endemic for ten years. He gives detailed account of his observations, dwelling specially on the cases that came under his care in the last locality. Here the disease appears in June, and subsides towards September; of 16 cases, 7 were of the pneumonic, 9 of the bubonic, type. Ten of these were treated with Roux's serum, 6 died, and 4 recovered. The pustular form described by several authors did not come under his observation. In the bubonic or Levantine type the virus probably enters through some solution of continuity in the epidermis, and the primary bubo is formed in the nearest lymph glands. A case is cited where the point of entrance was furnished by an ulcer on the breast, and the author also relates how in extracting the contents of a bubo with a syringe he had the misfortune to prick his finger; this was followed by pain in the forearm, rise of temperature, and *malaise*. He injected 60 c.cm. of serum, and the symptoms subsided. In the pneumonic form of the disease the virus enters by the nose or mouth; the mortality is higher than in the bubonic cases, and should the bacillus find its way into the general circulation in either form, death usually follows within twenty-four hours. In all cases examination of the blood shows a leucocytosis, and after a certain period it acquires agglutinative properties This last characteristic appears at the end of the first weeks, and is absent during the early days, so that it is useless as a diagnostic sign. During convalescence the blood is antitoxic. An attack of the disease confers immunity, and recurrence is rare. This immunity is much more certain than that conferred by the injection of serum or of dead cultures (Haffkine's method). Zabolotony thinks the serum of Roux preferable to Haffkine's prophylactic; it must be of standard strength estimated by testing its antitoxic power on animals. The preventive dose is from 25 to 40 c.cm., but as a curative agent the amount must be larger, from 50 to 100 c.cm. The essence of the process of recovery is the phagocytic activity of the leucocytes, and it is by stimulating and exciting this that the serum acts.

(78) A Parasite in Leukæmia.

Löwit (*Centralbl. f. allgem. Path.*, Bd. xi, No. 9, p. 315) describes a parasite which he has discovered in the lymphocytes in leukæmia. It is about one-sixth to one-third the size of a red blood cell, of a ring-like shape, and contains characteristic nucleus-like bodies and vacuoles. It is best demonstrated by staining with a strong solution of methylene blue. In rabbits infected with the disease the same bodies are found, but, whereas in man multiplication takes place by simple sporulation, in these animals a kind of sporocyst is formed resembling that of the malaria parasite. Löwit speaks of the organism as an amœba; he considers that the formation of a sporocyst in rabbits is due to the fact that the tissues of these animals are not favourable to the development of the parasite, and the symptoms of the disease are proportionately insignificant.

AN EPITOME

OF

CURRENT MEDICAL LITERATURE.

MEDICINE.

(79) Typhoid Fever Among American Soldiers.

Vaughan (*Philadelph. Med. Jour.*, June 9th, 1900, p. 1315), records the results of the investigation by a Board into the causes of the existence and spread of typhoid fever in the American National encampments during the time of the Spanish-American war. Every regiment in the service of the United States in 1898, both volunteers and regulars developed typhoid fever, and that, speaking generally, within eight weeks of going into camp. Typhoid became epidemic both in the large and in the small encampments. If any such disproof were needed these investigations disproved the miasmatic theory of the origin of typhoid, also the pyogenic theory, while they confirmed the doctrine of the specific origin of typhoid. If the men of any particular regiment did not bring typhoid from their homes there was ample opportunity of introducing it from other regiments. Its dissemination was shown to depend on the transference of the excretions of an infected individual to the alimentary canal of others. It is probable that immune individuals may carry and excrete the specific bacillus for a long time, and its longevity, both inside and outside the body, is much greater than is generally supposed. The likelihood of typhoid becoming epidemic is much greater in camps than in civil life, on account of the difficulty of disposing of the excreta. A man infected with typhoid may, indeed, spread the infection in every latrine of a regiment before the disease is recognised in himself. While some camps were unwisely located, and in others the space allotted to regiments was inadequate, many camps were allowed to remain on one site too long. As a general principle the number of cases of typhoid fever in the different camps varied with the method of disposing of the excreta. The tub system and the regimental pit system were both found unsatisfactory. It was recommended that, in permanent camps where water carriage could not be secured, all fæcal matter should be disinfected and then carted away from camp, preferably in galvanised iron troughs containing milk of lime. The evidence showed that infected water was not an important factor in the spread of typhoid fever in the camps in 1898, but flies undoubtedly acted as carriers of infection and that both in the way of mechanical transportation and in their digestive tract. It is more than likely that the men transported infected material on their hands or on their clothing and boots. Personal contact was undoubtedly one of the means by which the infection was spread and particularly so in tent life. It is probable that infection was disseminated to some extent through the air in the form of dust. A regiment badly infected with typhoid does not lose its infectivity by simply changing its location; indeed, it then carries the bacilli elsewhere in the bodies of the men, in their clothing, bedding, and tents. Even an ocean voyage was shown not to relieve infected regiments of their infectivity. It was recommended that the soldiers' beds should be raised from the ground, lifting them clear from infected dust. The overcrowding of tents should be avoided and medical officers should insist on soldiers removing their outer clothing at night whenever possible. About one-fifth of the soldiers in the camps in the United States in 1898 developed typhoid fever and the percentage mortality among these cases was 7·5 per cent. When a camp is thoroughly saturated with typhoid it is probable that from one-third to one-fourth of the men will prove to be susceptible to the disease. There was no evidence that dietetic errors or simple gastro-intestinal disturbance predisposed to typhoid. The shortest period of incubation in typhoid fever is probably something under eight days, and one who has lived in a camp in which typhoid fever is prevalent is liable to develop the disease any time within eight weeks after leaving it.

(80) Pneumonia.

De Dominicis (*La Clin. Med.*, An. 6, N. 26), lecturing on the pathogenesis and treatment of pneumonia, lays stress on the general nature of the disease, and teaches that the local lung symptoms are secondary to the blood condition, which in its turn is due to the alteration in the function of the digestive organs. On this view treatment is aimed at purifying the blood *viâ* the stomach and intestine. Mag. sulph., calomel, and other purgatives are given, and to disinfect the digestive canal fairly large doses of alkaline iodides are given, or sod. bit. or bic., which act as true expectorants by rendering the exudation more fluid and more easily detachable. The blood itself may even be washed by injection of physiological salt solution, but this is only of temporary value; the same applies to bleeding. As to the value of oxygen, the author is very sceptical. Serum-therapy holds out a better hope.

(81) The Uric Acid Diathesis.

A. Svorchotoff (*Russky Archiv.*, tom. v, May 31st, 1900) gives an analysis both of four cases of his own observations and of the more important and recent contributions and investigations made by other observers in connection with gouty affections; and has arrived at the following conclusions: (1) During the acute manifestations of gout, or during the later stages of the disease, when the patient is in a state of great debility, caused either by the occurrence of too frequent attacks or by great reduction in nutrition, clinical phenomena appear which unmistakably point to the vaso-motor system being largely involved. Coincidently a contraction, more or less spasmodic in character, of the smaller vessels may be observed. (2) Uric acid, varying in amount and rate with each individual, is deposited in and around the affected joints, and this not in the form of globules or calculi, as Pfeiffer specially maintains, but as needle crystals, which chiefly consist of biurate of sodium. (3) As regards the question whether the kidneys are capable of allowing albumen (in larger quantities) to filter through them during the acute stage of the disease, or while the depressing effects of the affection are well marked and far advanced, the author believes it to be the case. Moreover, he thinks this elimination of albumen by the kidneys may take place without—having regard to the pathological side of the question—any unfavourable consequences on the part of the secreting tissue of that organ. (4) Again, change in the general condition and the state of normal nutrition of the tissues, and possibly, also, alteration in the rate and amount of circulation through these structures, are the determining factors for the localisation of the gouty deposits in special tissues and organs. (5) As pointed out by former writers, that during an attack of gout, and particularly when the latter reaches its acme, both the quantity of urine and the amount of urea is noticeably diminished, while the rate of uric acid excreted is considerably increased: the author endeavours to confirm these observations. (6) With regard to the pathology of gout, the author is inclined to regard it as the result of a chronic autointoxication by the products of a morbidly altered metabolism; these abnormal bodies thus formed are in all probability closely allied to uric acid, and possibly contain also one of the bodies of the so-called xanthine group. (7) In conclusion, the author says that—at least in a large number of gouty patients—surgical interference becomes sooner or later inevitable, and is attended by good results.

SURGERY.

(82) Endothelioma of Bone.

Thévinot (*Rev. de Chir.*, June, 1900) publishes a full and instructive review of our present knowledge concerning a variety of morbid growths, to which much attention has lately been paid by surgical pathologists. By the term endothelioma, given to this form of growth, is designated a tumour developed at the expense of the endothelial elements existing in blood vessels or lymphatics, or forming the internal coat of serous cavities. Such growths may occur in any organ containing endothelial elements, and have been studied in the dura mater, in lymph glands, in the spleen, and, especially, in their favourite seats, the eyeball and the salivary glands. There seems to be no doubt that it occurs in bone more frequently than many pathologists have supposed, and that it has frequently been overlooked in supposed instances

of osseous sarcoma and aneurysm of bone. Any portion of the skeleton may become the seat of endothelioma. The morbid growth attacks both the long and the flat bones, and has been observed in the bones of the cranium and in the lower jaw, and in the femur, tibia, and humerus. It is usually developed in the spongy tissue, and, as a rule, involves the extremity of a long bone. The fully-developed growth, which is usually enclosed within a capsule, varies in different cases in consistence, being sometimes soft, and even fluctuating, at others firm and bony. On section the cut surface is of a deep red colour, resembling muscle. The growth on its surface presents a number of dilated blood vessels, and on its central part may often be found large cavities, probably formed by the communication of similar enlarged arteries and veins. The existence of these cavities, some of which are often as large as the hen's egg, accounts for the pulsation with *bruit* and the compressibility of the growth, which are such characteristic signs of osseous endothelioma. An important distinguishing character of the structure of an endothelioma is the complete absence of osseous lamellæ. The author describes at full length the histological distinctions between this morbid growth and such growths as osteo-sarcoma, angio-sarcoma, myeloid sarcoma, and carcinoma of bone. Endothelioma of bone may occur at any period of life between childhood and advanced age, and is not influenced to any marked degree by sex, there being but a slight excess of men over women. It is developed very insidiously, and without causing pain, so that in many instances attention has been first directed to the disease by the occurrence of a spontaneous fracture of the affected bone. The tumour, when well advanced in growth, presents a swelling, usually of small size, which is irregular over its surface, of variable consistence, some parts being soft and depressible, others of bony hardness, not adherent to the skin, and, even when seated in the epiphysis of a long bone, not involving the adjacent articulation. It is not accompanied by enlarged superficial veins, which present so characteristic a feature in cases of sarcoma. In course of time the disease involves remote parts of the body, usually other bones, in exceptional instances the lungs and pleura. The patient becomes weak and cachectic, and after an interval from the first appearance of the disease, varying in the list of recorded cases from 6 to 19 months, death results. Endothelioma, therefore, is to be regarded as a malignant tumour, which, if left to itself, will prove as rapidly fatal as sarcoma. The author, in his remarks on the diagnosis of osseous endothelioma, discusses the value of the sign of pulsation, which has been met with in about one-third of the recorded cases. This sign, which, he states, is common to endothelioma, angioma, and myeloid sarcoma of bone, should not lead the surgeon to consider the probability of the pulsatile tumour being an aneurysm of bone. Such term, he holds, does not imply a distinct and definite morbid growth, but is really a generic one, covering several forms of growth of varying nature and gravity. The treatment of endothelioma of bone, it is suggested, should consist of resection of the diseased structures, when the growth is small and still in an early stage, and in amputation or exarticulation when the tumour has attained a considerable size. The author seems disposed to prefer localised surgical treatment to extensive mutilation.

(83) Operations for Perforating Gastric Ulcer.

Lund (*Boston Med. and Surg. Journ.*, January 11th, 1900) reports a successful case, and adds a very useful table of statistics of 40 additional cases collected by himself, making all the published cases—Dennis to 1894, Cobb to 1897—amount to 181. The following analyses are specially important:

	Cases.	Recoveries.	Percentage of Recoveries.
Dennis (older cases) ...	43	10	23
Cobb (cases from 1894 to 1897)	98	50	51
Lund (1897 to autumn of 1899)	40	28	70

Thus the percentage of recoveries has steadily mounted up. Lund next analyses results of operation within twelve hours after the onset of symptoms of perforation:

	Cases.	Recoveries.	Percentage of Recoveries.
Dennis and Cobb... ...	45	35	78
Lund	14	12	86

These results should be compared with a third analytical table of cases operated upon within twenty-four hours:

	Cases.	Recoveries.	Percentage of Recoveries.
Dennis and Cobb... ...	70	49	63
Lund	26	19	73

Amidst cases operated upon days or weeks after perforation an occasional recovery is to be found, as the ulcer, whether on the anterior or posterior surface of the stomach, sometimes opens into a cavity walled off by adhesions. Localised abscesses—subphrenic, circumsplenic, etc.—result, and are finally opened and drained, with an occasional recovery. The urgency for immediate operation is very plainly demonstrated by these statistics.

(84) Prophylaxis of Syphilis.

Lang remarks that a complete knowledge of the biology of a disease need not of necessity precede the search for methods of immunisation against the disease; this is proved by Jenner's historical discovery. He suggests (*Wien. med. Woch.*, June 2nd, 1900) the possibility of certain experimental observations on persons in what he calls the post-initial stage of the disease, that is, between the stage of the initial lesion and the appearance of initial symptoms. A fresh infection may occur during this period, but it appears not to alter the course of the disease, so that experimental inoculations might be carried out without fear of untoward results. Experimental inoculations have already been made on themselves by some observers, but these can never be sufficiently numerous, and Lang suggests using prisoners who are undergoing long sentences and who would, he thinks, be induced voluntarily to undergo the inoculations in the interests of society, seeing that all danger might be eliminated by constant medical supervision and treatment. The author relates a case of syphilis transmission from a corpse during the performance of a *post-mortem* examination.

MIDWIFERY AND DISEASES OF WOMEN.

(85) Forceps Delivery of Live Child Fifteen Minutes after Death of Mother.

Egon Neumann (*Centralb. f. Gynäk.*, No. 10, 1900), in reference to Fleischmann's case of forceps delivery after death (*ibid.*, No. 4), publishes another which occurred as long ago as 1869, in the practice of his colleague, Dr. Koerbitz. That physician was called in suddenly to a shopkeeper's wife, and found her dead in labour. He sent at once for his instruments, which arrived in six minutes. Then he applied the forceps and delivered the corpse of a a female child, who lived and was reared. Delivery was completed just fifteen minutes after the patient's death. Koerbitz had never seen the woman before; she had suffered all through pregnancy with continually increasing dyspnœa and swelling of the legs. There was no *post-mortem* examination. The child showed no signs of asphyxia, and cried out well when delivered. The space of time after death was longer than in any of the three other cases of forceps delivery on the dead body (Fleischmann's case 10 minutes, Heinricius's 5 minutes, Piskacek's 5 minutes). Neumann also dwells on Fleischmann's practice in respect to parturient women, moribund or very ill from advanced pulmonary disease. The latter, just before the death of his patient, introduced one blade of the forceps after placing her in a half-sitting position as the orthopnœa was severe. Death occurred before he could pass in the second blade. Egon Neumann relates a somewhat similar case where premature labour was induced and the patient saved. She was a very sickly woman, aged 40, with

general anasarca and albuminuria. Orthopnœa was marked. The bougie was introduced, the patient being kept in the sitting position. In six hours the os being well dilated, perforation was performed and the fœtus extracted, without any flooding. Several assistants held up the patient, who was more dead than alive. Next day, the placenta was removed by expression. After delivery the patient seemed worse. Several incisions were made in the skin of the legs, and almost 2 pints of serum flowed away. Then she steadily improved, and the œdema almost disappeared. At the end of nine days she could ascend two steps unaided, and she ultimately recovered, though with permanent morbus cordis.

(86) Arrested Labour from Distended Bladder in Fœtus.

Couvelaire (*Bull. et Mem. de la Soc. Anat. de Paris*, March, 1900) reports the delivery a little before term of a primipara, aged 24. Pregnancy had been normal. When she was admitted into hospital it was not certain how long the waters had escaped. There was slight albuminuria. The occiput presented to the right posteriorly, and there was some difficulty in delivering the head. Then the shoulders could not be extracted, even when the posterior arm was lowered. The child died during these manœuvres. The head midwife drew down the anterior arm, but the humerus was fractured and the shoulders remained fixed. On exploration the thorax appeared normal, but the abdomen was much swollen, and fixed above the pelvic inlet. The trocar was used, and 550 grams of fluid came away; it was clear, lemon-yellow in colour, and highly albuminous. Then the child was easily extracted. It weighed, excluding the urine already removed, over 6½ lbs., and measured 18¾ inches; the biparietal measurement was 3½ inches. It was a female. The distention of the abdomen was due to retention of urine. The cause of the retention could not be detected; there was no malformation, and the urethra was quite free from stricture. The ureters and renal pelves were dilated. Gaüdon, Cornelli, and Lefour have reported similar cases where no stricture existed. In Porak's case the obstruction was due to a valvular fold in the mucous membrane, which Hergott of Nancy suspects must exist in all such cases, but is easy to overlook. As a rule retention of urine is due to complete congenital stricture.

(87) Placental Transmission.

Dorland (*Amer. Gyn. and Obst. Journ.*, June, 1900) reviewing the literature of the placental transmission of drugs and specific diseases, finds that certain drugs—not all—show a tendency to traverse the placenta and entering the placento-fœtal circulation exert a positive influence for good or evil. Maternal medication is therefore indicated in certain conditions. The drugs which most notably affect the fœtus are opium, mercury, copper, lead, arsenic and the iodides. In appropriate doses they may be administered to the mother in suitable pathological conditions, with beneficial results to mother and child. Any morbific influence acting on the mother either acutely, as in the case of the exanthemata, or more slowly, as in tuberculous and specific infection, will react deleteriously on the product of conception and either destroy it through its overwhelming toxic action and render it feeble and less resistant to subsequent and postnatal invasion, or the disease will run an atypical course during uterine life with or without apparent vestiges at birth. The entrance into the fœtal structures is accomplished through the agency of a fœto-placental circulation. It is probable that access is gained through bacterial action, the germs rendering the placental villi less resistant to invasion, whereas both the microbes and their toxin pass the natural barrier at the chorio decidual junction. As a rule, infectious diseases do not manifest their characteristic visceral lesions in the fœtus, probably because of the passivity of these organs before birth. The germs, however, may be detected in large numbers by bacteriological and microscopical examination.

(88) Puerperal Eclampsia and Cerebral Hæmorrhage.

Boissard (*Bull. de la Soc. d'Obstét. de Paris*, February 15th, 1900) observed a case of this kind where, though albuminuria was marked, the fits did not seem severe. Prognosis is ever uncertain in eclampsia; repeated fits and long periods of coma do not always end in death, and after delivery the obstetrician often thinks that recovery is certain if the slightest amelioration occurs within a few hours. In Boissard's case the patient had three fits, and seems to have been but slightly comatose. Delivery was effected speedily, and the coma began to pass off. Six hours after delivery two fits occurred. Venesection was performed, but three hours later the patient died. The rapidity of death after the fits suggested cerebral hæmorrhage. Free hæmorrhage was discovered on the surface of the convolutions of the left hemisphere. There were also very widely distributed hæmorrhages in the liver, subscapular, interlobular, and intralobular. Bar, in discussing this case, declared that cerebral hæmorrhages were common in eclampsia. Schwaab recalled his case, where temporary hemiplegia occurred. Maygrier spoke of his more recently reported case where sudden and rapidly fatal asphyxia was caused by cerebral hæmorrhage, which nearly destroyed the bulb and the floor of the fourth ventricle.

THERAPEUTICS.

(89) The Treatment of Epilepsy.

Fleury who has made a careful study of the treatment of epilepsy (Abstract in *Journ. de Méd.*, May 10th, 1900), strongly believes in the autotoxic nature of this neurosis, and therefore considers that diet forms one of the most important elements in the treatment of epilepsy, and should be combined with methods tending to free the gastro-intestinal tract from toxic material. Fleury admits that some cases of epileptic seizure seem to be directly due to lesions, meningeal and otherwise, of the central nervous system, and such accordingly are very difficult to treat, but many others, and by far the greatest number, show no cerebral lesion other than possibly some inherent excitability, but in whom disorders of circulation, be they due to autointoxication or reflex irritation, are the cause of the seizure. These seizures may vary in very many respects, under the influence of diet, suppression of alcohol, etc. Patients so affected must have their diet carefully regulated and all the surroundings modified, and after this bromides may be administered. These latter become more efficacious when patients have been properly prepared for their exhibition. The writer points out the extreme frequency of gastro-intestinal disorders (possibly dilatation of the stomach), atony of the intestine, and constipation. Indicanuria is also a frequent feature. Such patients are put on dry toast, boiled eggs with ham, light fish, such as sole, whiting, veal, chicken, beef, and mutton in small quantities for the first midday meal, and an extremely reduced quantity at night, the last meal being preferably vegetarian. Dry cakes, biscuits, one or two glasses of water, especially mineral or hot water, should constitute the only beverage, alcohol being contraindicated. Euonymin, cascara, and similar drugs should be freely administered, while copious enemata should be given daily. Should there be any extreme dilatation of the stomach this organ should be washed out. Under such conditions of diet the bromides, especially the bromide of soda, will render much service. Chloral has also been found of much use. The administration of bromides should be relegated to the time of the seizures according as they are nocturnal or diurnal. In the case of daytime fits bromide should be administered before each meal. Massage, cold douching, brine baths, and mountain air are all more or less of great importance. The injection of an artificial serum, consisting of 1 per cent. of phosphate of soda, sulphate of soda, chloride of sodium, and carbonic acid, is useful. Eight to 10 grams of this may be administered daily by hypodermic means. According to the writer some weeks of such treatment should stop any tendency to epileptic seizure.

(90) Dormiol as a Hypnotic.

Schultze (*Neurol. Centralbl.*, No. 6, 1900) describes the results from the use of dormiol in various kinds of insomnia. Dormiol is a compound produced by the action of chloral on amylene hydrate, and in a 10 per cent. aqueous solution is colourless, and has a menthol-like odour, and a similarly cooling taste. His observations were made at the Andernach Asylum on patients suffering from various forms of mental and

nervous disease, and, in all, he has administered it over a thousand times. It was found to be effective in producing sleep and rest in 75 per cent. of the cases, and was particularly effective in melancholia and hypochondria, where it acted like magic. The sleep produced by its use lasted from five to eight hours, and neither unpleasant after-effects nor any depression of the cardiac action or circulation followed its use. In a few cases of hypochondria, however, the patient complained of some headache the day following its use. The usual dose was from 20 to 40 minims, never exceeding 45 minims. As regards hypnotic efficiency, Schültze places dormiol on or about the same level as sulphonal or trional, and makes the observation that one may succeed where the other fails. He lauds it especially for the remarkably excellent effects it gives in melancholia and hypochondria.

(91) The Treatment of Chorea.

LÉVY has published some investigations on this subject (*Thèse de Lyon*, 1900). It has already been pointed out by Aran and F. Siredey that arsenic in large doses will generally cause rapid disappearance of chorea. The drawback is that occasionally vomiting and diarrhœa supervene. Some experiments performed in 1879 by Chapuis have shown that arsenic when combined with butter appears infinitely less toxic than when given in solution. These investigations have been repeated by Lévy working with Weill. This author finds that the amount of butter should be invariably fixed to 10 grams whatever the quantity of active principle incorporated with it. To prepare the mixture a known quantity of arsenious acid is taken according to the dose to be administered. To this is added sodium chloride in such proportion that 0.1 gram corresponds to 0.005 of arsenious acid. This mixture must be very perfect, as on it depends the accuracy of the dosage of arsenic contained in the given amount of the butter, and the proportion must be maintained according as the dose of arsenic is greater or less. This mixture of sodium chloride and arsenic is triturated with 10 grams of fresh butter, and this amount is given spread on bread, a form of medication which is extremely palatable to children. One of the chief points is that the drug must never be administered while fasting. Experimentation has shown that when arsenic is given to dogs while fasting they very soon showed symptoms of arsenical poisoning. The writer finds that the best results were obtained when arsenical butter was administered during a meal. The whole dose should be given at a time, but two doses a day seem to be sufficient. It would seem from the writer's investigations that under this method of treatment it is not even necessary to confine the patient to bed or to put him on a milk diet, and that as a matter of fact a more liberal diet gives better results. This method of dosing can even be confided to inexperienced hands. Another point is that the same dose can be administered to children of almost any age. Lévy seems to prefer a somewhat rapid increase of the dose of arsenic, and from his numerous observations he appears to have obtained some very excellent results.

(92) Fersan.

SILBERSTEIN (*Therap. Monats.*, July, 1900) reviews the various methods which have been recommended for the administration of iron, the number of which indicates that no one of them can give universal satisfaction. He gives a full account of the latest ferruginous drug, fersan, which was first made by Dr. Adolf Jolles of Vienna. It is produced by centrifugalising whipped blood and treating the separated red blood corpuscles with concentrated hydrochloric acid. There are thus formed a histon-like base and an acid-albumin containing all the iron and phosphorus. It is a chocolate-like powder with a slightly salt taste, is perfectly soluble in warm water and does not coagulate on heating; it contains more than 80 per cent. of proteid and is absolutely free from alloxan bases and other products of proteid katabolism. Winkler showed that its administration to animals caused an increased deposition of iron in the liver and spleen, and Kornauth proved its inhibitive value by giving it to healthy men. Silberstein has used it in cases of anæmia in primary and tertiary syphilis, of severe early syphilis and of anæmia following uterine hæmorrhage, also as a nutritive agent in children convalescent from acute specifics. He reports that the results obtained were uniformly good. As fersan is not acted on by artificial gastric juice it is probably absorbed only from the intestine, and that the absorption is very complete is shown by the fact that the fæces are not coloured by ferric chloride as after the administration of other iron salts. The adult dose is 3 to 6 teaspoonfuls a day, but 3 ounces a day have been given to a man for some weeks without ill-effect. The author lays great stress on the entire absence of all secondary consequences, which are so frequent a drawback with other iron preparations.

PATHOLOGY.

(93) Etiology of Pneumonia.

MME. N. SCHULTZ (*Arch. des Scien. Biolog.*, tome viii, No. 1) records some experiments on the mode of infection by Fränkel's diplococcus. Hitherto it has been almost universally held that the organism gains entrance to the lungs by the respiratory channels, and that some tissue change, such as that produced by chill, is necessary to determine their characteristic pathological activity. In 1893 Ouskoff stated his opinion that the pleurisy and pericarditis which not infrequently accompany pneumonia are due not to infection by continuity, but to the fact that the virus is in the blood. The diplococci have since then been detected by several observers in the general circulation and in the different organs of the body, especially in the more acute cases of the disease. Mme. Schultz used rabbits for a series of experiments, and introduced the organism directly into the jugular vein. Out of 14 animals thus inoculated, pneumonia resulted in 8, and microscopical examination showed the usual exudation of fibrin, hyperæmia, and leucocytosis, and the presence of the diplococci in large numbers. The experiments show that no antecedent alteration in the lungs is essential to the incidence of pneumonia, but that the disease may result from infection of these organisms through the blood stream, the pneumococci finding here the most favourable site for their multiplication and for the development of an active virulence.

(94) Influence of Sterilised Air on Animals.

KIJANIZIN (*Archiv. d. Biol.*, tom. xvi, p. 663) in 1894 published some researches on the influence of bacteria in the intestinal canal on the assimilation of nitrogen, and showed that in their absence the amount of this element absorbed is considerably lessened. This is to be explained on the ground that these organisms are capable of aiding peptonisation and the breaking up of albumen by their fermentative action. In the course of these experiments he found that if he confined animals in a chamber to which only sterilised air was supplied some died after a few days of this confinement, others though taken out alive died shortly after, and the rest showed symptoms of extreme lassitude and weakness. These results were proved by the author not to be due either to starvation or to the exhalation of any toxic matter by the animals, or to the presence of any carbonic oxide in the sterilised air, and the present series of experiments was undertaken to elucidate the problem. Analysis of the urine of the animals thus confined showed that the quantity of leucomaines, which are the products of incomplete oxidation of albumen, was largely increased, while the proportion of urea, the product of complete oxidation, was much decreased. In other words the oxidation processes which normally go on in the tissues themselves were found to be considerably interfered with by the exclusion of organisms from the respired air. Reference is made to the experiments of Gautier, Ehrlich, and others which have shown that in the processes of oxidation which take place in the tissues themselves certain ferments, hitherto undefined, are the active agents; the author's observations point to the fact that these ferments are supplied by bacteria which gain access to the blood and probably to the leucocytes in the lungs. The actual cause of the debility and death in the animals is the enormous accumulation of insufficiently oxidised products which exercise a toxic influence. Kijanizin in fine states his conviction that in addition to the oxygen of the air certain micro-organisms normally present therein are necessary to life; that by gaining access to the blood they aid in the ultimate oxidation processes in the tissues, and that in their absence imperfectly oxidised products accumulate and cause death.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF INTERNAL MEDICINE.

The first question on the programme of this Section was the Pathogeny of Gout. The discussion was introduced by Dr. Le Gendre, Physician to the Tenon Hospital, Paris, Sir Dyce Duckworth, and Professor Wilhelm Ebstein, of Gottingen. The following are abstracts of their reports.

(95) The Pathogeny of Gout.

Dr. P. Le Gendre said that since the uratic nature of tophi and urichæmia in gouty subjects had been determined the efforts of theorists had almost always had as their object an explanation of the pathogeny of gout by accumulation of uric acid in the economy and the precipitation of urate of soda in the tissues. The author rapidly reviewed the principal theories, namely, the introduction in excess of uric acid by the food or of nitrogenous substances generating uric acid; the formation in excess of uric acid by destruction of the nucleins or nucleo-albumins proceeding from the leucocytes or from the nuclei of all the cells in the body; the accumulation of uric acid by insufficiency of transformation into urea whether through torpidity of the liver or default of a ferment permitting it to fulfil its uropoietic function, or by inadequate oxidization throughout the organism; the retention of uric acid in the blood by insufficiency of the eliminatory function of the kidney; the resorption of uric acid in the kidney, which being supposed normally to have the function of effecting by certain of its cells the formation of uric acid by combination of the urea and glycocol proceeding from the liver, would become incapable of eliminating the acid formed. This being reabsorbed would in the blood become quadriurate of soda, which being present in superabundance precipitates itself under certain influences in the tissues in the state of biurate of soda. Some hold that the presence of urate of soda in the articular tissues sets up therein only a paroxystic inflammatory reaction as a foreign body. Others maintain that the uric acid acts as a chemical poison causing necrosis, and that the preliminary mortification of the tissues is necessary to the formation of the crystallised uratic deposits. Some explain the gouty localisations by the smaller vascularisation or the less resistance of predisposed tissues and the onset of attacks by the hindrance of the renal functions. Others attribute the localisations, paroxysms, and metastases to a nervous influence. It has also been believed that uric acid was hurtful only after having undergone certain physical or chemical modifications, and that a pathogenic *rôle* should be attributed equally to substances other than uric acid, such as alloxuric bodies. Each of these theories is open to valid objections, chemical, physiological, or pathological; the most plausible, moreover, can explain only the mechanism of the gouty paroxysm, not the permanent and hereditarily transmissible disturbance of cellular transmission, which is the necessary link between the intermittent morbid phenomena in the individual as between the disease of the father and that of the son. Clinical statistics, however, have placed it beyond question that gout is observed with a special frequency in individuals whose ancestors or descendants suffer from diseases of the so-called arthritic group or from trophic inadequacy. First, diabetes and obesity, and that gout is often associated with some of these diseases in the same person. The numerical relations established between diseases of the arthritic group warrant us in attributing to each of them the pathogenic process which has been shown to be true as regards one of them by Bouchard, after whose investigations it is no longer permissible to doubt that diabetes consists in a diminution of the aptitude of the tissues to burn up sugar, to carry to the extreme the transformations of carbohydrates. If clinically gout is of the same nature as diabetes, there is a great probability that there exists in the gouty subject a defective elaboration of nitrogenous material, an inaptitude of the tissues to destroy albumin thoroughly. Among the consequences of the incomplete destruction of refuse must be included the incumbrance of the organism both by certain acids (oxalic, acetic, lactic, etc.), which can diminish the conditions of solubility of uric acid without that substance being necessarily in excess in the blood, and by certain organic bodies the toxicity of which may contribute to the production of the manifold accidents of gout. Clinical statistics further place in evidence the morbid affinities of gout with simple albuminuria and interstitial nephritis as the frequency and intensity of the disturbances in gouty subjects. It may be inferred from these coexistencies that the functional disturbances of the kidney, as those of the nervous system, play a part in the preparation of gout and in the outbreak of its paroxysms, either by hindering the eliminations of the toxic waste products of the denutrition of the tissues, or through neurotrophic inhibition of the intracellular metabolism. When gout is acquired, the nutritive disturbance of the cells is brought about by a defective hygiene (abuse of food stuffs, nitrogenous or rich in oxalic acid, and of certain fermented drinks, insufficient physical activity, and overstrain of the nervous system), or by the action of a poison (lead). When gout is hereditary it is that the nutritive disorder of the cells of the first begettor has been continued through the ovum or the spermatozoon in the descendants of these cells.

Sir Dyce Duckworth read a paper, of which the following is a summary: (1) That gout as a morbid condition depends on an inherent vice of nutrition, which is manifested by an imperfect metabolism in various organs or parts of the body, presumably in the kidneys, and probably in the liver. (2) That this trophic disorder or inadequacy leads to the formation of uric acid, probably in excess, and to the periodic retention of it in the blood (gouty urichæmia). (3) That histology throws no light upon the intimate nature of this defect, which thus relates to cellular potentiality, possibly under neurothropic influence, and not, as far as we know, to structural alteration. (4) That this textural disability, or a tendency to it, may be primarily acquired, and also transmitted as a fault, thereby inducing from time to time urichæmia with gouty manifestations in the descendants. (5) That in most instances, under conditions which provoke it and in some cases independently of these, attacks of gout may grow up and come to a crisis. Such crises are attended by an alteration in the solubility of the uratic salt in the blood, whereby irritating crystals of biurate of sodium are produced and precipitated in various parts of the body. (6) That a paroxysm of gout, the sites of its occurrence, and its metastases, are determined by nervous influences, probably dominated from the bulbar centre, and that the local attacks alight either in the joints or in textures which have been weakened or rendered vulnerable by impaired nutrition, owing to past injury or overuse. (7) That this central neurosis is an essential and transmissible feature in the pathogeny of gout, and pertains to the arthritic diathesis generally. (8) That the urichæmia of gout is peculiar and unlike that which is induced by other morbid conditions, but that the occurrence of urichæmia in the gouty is by itself inadequate to induce attacks of gout. (9) That uratic deposits in any part of the body may be removed in course of time, but are apt to be permanent in the least vascular tissues. (10) That uratic deposits may occur to an enormous extent in gouty persons without the occurrence of any pain or paroxysms. (11) That the clinical features of gout indicate that both hæmic changes (due to inherent morbid tissue metabolism) and a neurotrophic disturbance act as pathogenic factors, and that, consequently, gout is to be regarded as a neuro-humoral malady.

Ebstein summed up his conclusions as follows: (1) Gout is a more or less chronic disease of which the fundamental substratum is a hereditary morbid proclivity, which is almost always congenital. To this proclivity is given the name "uric acid diathesis." (2) As regards ultimate cause of the uric acid diathesis, nothing more than hypothesis can be advanced. The intimate relations existing between the nucleins and uric acid make it probable that we have to do in the uric acid diathesis

with an abnormal state of the cell nuclei or of the protoplasm of the individual proclivity, which can be followed throughout whole generations and races of men is in any case of the greatest importance in the uric acid diathesis. (3) It appears that there are various circumstances which may contribute to the development of the diathesis and its transformation into positive gout. Among these circumstances must be mentioned the following: (*a*) Gout develops, all the circumstances being alike, the earlier and more intensely the diathesis is more pronounced; (*b*) there are habits—laziness, luxurious living, often a combination of both these causes, in the highest degree the abuse of alcohol—which favour the development of gout; the temporary variations that have been observed may generally be attributed to those circumstances; (*c*) there are acute and chronic intoxications, which, given the existence of the diathesis, favour the development of gout; bacillary poisons are in that case of great importance; relations of gout with rheumatism, syphilis, and lead poisoning should in the first place be borne in mind: influenza, too, seems to favour the appearance of gout; (*d*) contagion, which was considered a factor of the first importance by Boerhaave, appears to be of no importance; (*e*) climate seems to have no influence. (4) Uric acid seems to be the poison (the *materia peccans*) of gout. The question of knowing whether or not, besides uric acid, other products of the organism belonging to the family of the alloxurs or nuclein bases play a part is still unsettled. It is probable that it is only the uric acid formed at the expense of the nucleinic substances of the human body and not that formed at the expense of the nucleins of the elements which has an influence on the pathogeny of gout. It has not yet been proved that in gout uric acid is formed in excess, and Ebstein does not think that this is indispensable. Nevertheless he thinks that an excess of uric acid is very probable. The history of leukæmia teaches that gout is not the result of increased production of uric acid (estimated according to the quantity of uric acid separated in the urine) for there is in some cases of leukæmia a secretion of uric acid such as is never seen to such a degree in gout. (5) Uric acid is a chemical but not a septic poison. The influence of the poison is not equal either on different animal species or on animals of the same species differing in age. Inflammatory and necrosing changes of the tissues in question are the necessary consequence of the presence of uric acid, which finally causes a complete necrosis. When the tissues are utterly dead, but not before, the acid is deposited in them in the form of crystalised acid urate of soda (mono-natrium-urate, Tollens), (sodium biurate, Roberts). Tollens thinks that the uric acid circulates in the blood and the alkaline juices of the human body in that same form and not, as Roberts has supposed, as sodium quadriurate (called more rationally hemi-sodium-urat by Tollens). It may be admitted without hesitation that the mono-natrium-urate (Tollens), natrium-biurate (Roberts), may be deposited in a crystalline form in the tissues necrosed either by uric acid or another poison. (6) To understand the pathogeny of the different symptoms of gout one must assume (*a*) a primary articular gout; (*b*) a primary renal gout. The former is the most widespread form of gout which does not prevent its subjects from reaching an advanced age. Primary articular gout develops itself first under the influence of a retention of uric acid; this retention is localised because it effects only one or more parts of the human body. In primary renal gout we have to do from the first with a generalised retention of uric acid, which consequently affects all parts of the body; it is always caused by a primary and material change in the kidneys.

(96) Diagnosis of Renal Insufficiency.

This subject was introduced by C. Achard, who said that the diagnosis formerly rested entirely on a complex of general and functional disturbances, such as uræmic phenomena—dropsies, slight signs of "Brightism," *bruit de galop*, and a summary examination of the urine consisting in the estimate of its volume and density, and the discovery of albumen and casts. Thanks to the simplicity of the investigation, and the long experience acquired with regard to them these signs still remain the primary conditions of every renal affection. But they are better fitted to establish the existence and the nature of the lesions of the kidney than to make known functional disturbances of these organs. The anatomical change and physiological disorder do not always proceed *pari passu*, and on the other hand the functions of the kidneys may be seriously compromised even when the preceding symptoms remain unpronounced. A deceptive appearance of general health is maintained, and a more or less precarious compensation masks the danger—which is nevertheless very real—that threatens the organism. Therefore some complement of the investigation into the state of the function becomes necessary. To this end a whole series of researches has been devised, having for their object the exploration of the urinary secretion especially by comparing the urine and the blood, by various procedures, clinical (dosage) physical (cryoscopy) and physiological (toxicity). Moreover, instead of studying the product of the spontaneous secretion of the kidney it has been proposed to inquire how that organ accomplishes a work set to it to do, consisting in the induced elimination of a foreign substance introduced in a known dose into the organism. Of the methods referred to, only two are sufficiently practical—cryoscopy and induced elimination. The comparative cryoscopy of the urine and the serum which affords knowledge of the number of the molecules without distinction of nature contained in the two fluids, indicates the permeability of the kidney combined with the dosage of certain ingredients of the urine, the measurement of its amount, and the estimation of the weight of the body, it appears capable of also furnishing very instructive information as to the state of the renal circulation and the nutrition as a whole. Achard, however, thinks it possible that the ingenious calculations which allow us to draw all those deductions are somewhat wanting in the simplicity necessary for everyday practice. As regards the test of induced elimination which is generally carried out with methylene blue, it enables us to judge within what limits of time, and in what proportion the kidney accomplishes the disincumberment of the organism from the substances for which it serves as the emunctory. Differing in their mechanism, those explorations may furnish somewhat dissimilar indications. It is advantageous, therefore, to combine them. They are interesting in a double respect. First, they constitute a method of study applicable to pathogenic researches, and are suitable for the elucidation of certain obscure points in the domain of theory. Next they have a practical utility, for they confirm by making more precise the data acquired by simple clinical examination, as it is carried out cursorily at the bedside. Sometimes even they suffice for the detection of disorders of the renal function which would have remained uncertain or unknown; this is especially the case in certain cases of interstitial nephritis running an insidious course.

S. Laache in his report treated the question from the clinical and the therapeutic point of view. He took for his starting-point the function by virtue of which the kidney is the most important secretory apparatus of the organism for waste matters, liquid and solid, the last being represented chiefly by urea. He referred to renal œdemas, *œdema fugax*, general anasarca, and the decisive part played by the heart. As regards diagnosis, in connection with which he alluded to the milder form of Bright's disease, he said the researches of Achard and Castaigne had opened up a new way. Treatment should be by preference prophylactic; but if this was impossible, the well-known principles already followed in the treatment of renal affections should be applied. Special attention should be given to the state of the heart.

(97) Treatment of Muco-membranous Colitis.

Dr. Albert Mathieu, physician to the Hôpital Andral, Paris, said he would confine himself to a summary review of the principal pathogenic and symptomatic indications, and the broad lines of treatment corresponding thereto. (1) Constipation is the rule in muco membranous colitis; it is often spasmodic. The diarrhœa, which is always transient, is the result of a *débâcle* or an attack of catarrhal colitis. (2) There always exists in muco-membranous colitis a secretory irritation of the mucous membrane. (3) The syndrome muco-membranous colitis does not occur in its full intensity except in individuals predis-

posed by a pre-existing neuropathic condition. The colitis tends to aggravate this neurosis, and localise it in the abdomen. The same holds good with regard to visceral ptoses. Locally, the neurosis induces hyperæsthesia of the walls of the large intestine and disorder of its motility; it is especially a cause of spasmodic contractions. (4) The general and local conditions very often react on each other in muco-membranous colitis, and reciprocally aggravate each other. In treatment both these elements must be kept in view. Disorders of alimentation, attacks of pain, doubtless also autointoxication, are a cause of anæmia, wasting, sometimes even true cachexia. (5) Lastly, certain complications, acute dysenteriform or febrile attacks, hæmorrhage, etc., furnish special indications for treatment. The constipation is at once a cause and an effect; before everything, the removal of this condition must be aimed at, its disappearance is the sign and guarantee of the cure of muco-membranous colitis. In dealing with it measures must be employed that do not increase either the secretory irritation, the pains, or the tendency to spasm. Castor oil, large enemata, and belladonna are especially useful. The castor oil should be given in the morning in small doses with the early breakfast, its employment should alternate with that of the large enemata; these should be given at a low pressure, slowly and at a temperature near 104° F., in doses of 1½ to 2½ litres. These enemata soothe the painful and spasmodic irritation of the intestine, bring about the evacuation of material accumulated within it, and act as a mechanical antiseptic. Boiled water may be used, with a weak solution of biborate or salicylate of soda to reinforce the antiseptic action, and a very dilute solution of neutral ichthyolate of ammonia to exert a modifying action on the intestinal catarrh. Care must be taken to avoid everything likely to cause irritation of the bowel; for instance, drastic purgatives, astringent injections, massage in the cases where there is marked hyperæsthesia of the intestine or painful spasm of the colon. It has sometimes been recommended that food rich in vegetable detritus—green vegetable, cooked fruits, wholemeal bread, etc.—should be given; in many cases, however, this is not tolerated, and one is obliged to prescribe a regimen that favours constipation but lessens the irritation of the digestive mucous membrane. Enemata of oil are often very useful, especially combined with large enemata at low pressure. Belladonna is often prescribed with success; it soothes pain, and antagonises the tendency to spasm. More rarely one may have recourse to opium and its derivatives. Hot local applications and hot baths have a useful sedative effect; prolonged baths and large hot enemata form the basis of the treatment at Plombières and similar stations. Sometimes in these places ascending douches given at too high a pressure have been abused. It is often also of advantage to act on the general neurosis by the employment of nerve sedatives and hydrotherapy; often the patients are weakened and emaciated, and it is necessary to raise the standard of their nutrition, and at the same time to prescribe a regimen more appropriate to the state of their digestive canal. The dysenteriform attacks should be treated with enemata of a weak solution of nitrate of silver; the hæmorrhages by preparations of hamamelis and large enemata at a temperature of 113° F.

F. Boas (Berlin) next dealt with the symptomatology, diagnosis, and clinical course of muco-membranous colitis: (1) By muco-membranous colitis is understood a special catarrhal disease tending to plastic mucous formations of the colon; (2) in addition to this form, which is the most frequent, there is another much more rare, in which the process manifests itself in paroxysms, whilst in the intervals there is no noticeable malady except constipation; this form is denoted by the term mucous colic; (3) lastly, there is a third form which may be designated by the name of artificial muco-membranous colitis; by astringent injections, especially tannin, this form may be induced in persons who are the subjects of colitis, but not in healthy individuals; 4) the symptomatology of muco-membranous colitis includes constipation, colic, spasmodic atony of the intestines, glairy or membranous masses in the stools, and a general neurotic state; nevertheless, several of the symptoms may be wanting, the only one of them that is almost constant is constipation; (5) that which alone determines the diagnosis is the existence of characteristic mucous masses, the other symptoms—sensitiveness of the colon, coloptosis, movable kidney, and atony of the intestine—at the most can only help to confirm the diagnosis; (6) it is indispensable that it should be ascertained whether the muco-membranous colitis is an idiopathic condition or a complication; it is equally of great importance to ascertain whether the membranous colitis is of artificial origin; (7) in regard to the differential diagnosis the only alternative that need be considered is mucous colic; by frequent observations and methodical intestinal injections in the intervals it will almost always be possible to come to a decision; (8) the clinical course of muco-membranous colitis is absolutely parallel to that of habitual constipation; influences which correct the latter will cause the former to disappear, and *vice versâ*.

Dr. Julius Mannaberg, Physician to the General Polyclinic, Vienna, dealt with the pathogeny and pathological anatomy of enteritis membranacea and colica mucosa. (1) A distinction must be made between membranous enteritis and mucous colic. (2) By membranous enteritis is understood a subacute or chronic catarrhal affection of the large intestine, accompanied by evacuations particularly rich in mucus. (3) By mucous colic is denoted a morbid state of which the special clinical symptoms are: Paroxysmal crises of colic followed by evacuation of masses of mucus. (4) It is a question whether the two processes may occasionally be combined. (5) Each of the two morbid forms of which the only common element is the existence of mucous evacuations has a pathogeny peculiar to itself. (6) The first form is nothing more than a catarrh of the large intestine characterised by an abundant evacuation of mucus; it has the same pathogeny on the whole as ordinary catarrh of the large intestine. (7) Mucous colic on the contrary has a special pathogeny. In the great majority of cases it rests on a basis of general neurosis (hysteria, neurasthenia), and there is a tendency to consider the disease as an expression of the neurosis. In the exceptional cases where there is no underlying general neurosis the morbid state must be regarded as a mono-symptomatic neurosis of the intestine. In addition to this fundamental etiological factor certain occasional factors capable of producing paroxysms must be taken into account. The principal among them are diseases of the genital apparatus (in man as well as in woman), mental disorders, constipation, irritating rectal irrigations, organic diseases of the intestine. (8) Mucous colic is frequently accompanied by other pathological manifestations to which its production cannot be attributed, but which may be regarded as equivalents of the fundamental nervous element—gastric achylia, nervous dyspepsia, spasmodic constipation, enteroptosis. (9) The pathological anatomy of membranous enteritis is the same as that of enteritis in general. (10) As regards mucus colic in the very rare cases in which it has been possible to make an examination either on the living or the dead body no appreciable lesion of the mucous membrane has been found.

---

(98) Pulmonary Œdema.

Professor von Basch (Vienna) dealt with this question under the following heads: (1) Under what conditions is pulmonary œdema produced? What is the nature of the process producing it? (2) What are the secondary consecutive processes? (3) What relation is there between the doctrine of pulmonary œdema and that of dyspnœa and cardiac asthma? What relation is there between pulmonary œdema and muscular insufficiency of the left heart? (1) The first pathogenic condition of œdema is that the capillary circulation of the alveoli should be arrested owing to the elevation of the blood pressure in the left auricle. The second is that the afflux of blood coming from the right heart, that is to say, from the side of the pulmonary arteries, should be unimpeded. The mechanical consequences of these two conditions are the enlargement of the pulmonary alveoli and increase of resistance in their walls. The enlargement is produced by elongation of the capillary vessels and the increase of resistance by the high tension of the blood in the capillary network. To these two consecutive processes may be added transudation into the alveoli—a natural consequence of the circulatory stasis in

the lungs. (2) The enlargement of the alveoli and the increased resistance of their walls create a mechanical obstacle to respiration, and as a consequence a disturbance in the ventilation of the blood. From this arises a morbid sensation, dyspnœa, which is only the expression of the disproportion between the work of respiration and its effect. This morbid sensation becomes intensified proportionately to the increase of carbonic acid which accumulates in the blood as a result of the disturbance of its aëration. It causes an increased excitement of the respiratory centres and forced labour of the respiratory muscles. The obstacle increases still more when intra-alveolar transudation is added to the preceding conditions—enlargement of the alveoli and increased resistance of the lungs. There is need to insist on the fact that the transudation alone without concomitant enlargement of the lungs does not hinder respiration so much as is believed. An abundant transudation, if it is associated with a slight pulmonary enlargement and moderate resistance of the lungs, produces much less dyspnœa than a slight transudation combined with a considerable enlargement of the lungs and a strong resistance of the alveoli. The persistence of the dyspnœa causes an increase of carbonic acid in the blood. The result is death of the heart in consequence of general asphyxia. (3) The dyspnœa and cardiac asthma develop in the prodromal stage of pulmonary œdema, that is to say, before the production of the alveolar exudate; but a slight transudation is very difficult to discover by clinical examination, and it is probable that it accompanies both these diseases equally. (4) Cardiac dyspnœa, cardiac asthma, and pulmonary œdema have their starting point in muscular insufficiency of the left ventricle, and not merely in primary insufficiency, which is characterised by a low arterial pressure, but also in secondary insufficiency, which is characterised by increase of arterial pressure.

Professor Masius of Liège dealt with the pathogeny of acute pulmonary œdema. Œdema, he said, is an abnormal accumulation of lymph in the plasmatic spaces. Acute pulmonary œdema is only a particular form of it, presenting two peculiar characters, both depending on the acuteness and activity of the pathogenic process and its particular localisation. These, are first, the accumulation of the liquid not only in the lymphatic tissue, but also and particularly in the alveolar cavities by transudation through the walls or by rupture of these; next, the suddenness with which the phenomena show themselves on which depends the almost uniform clinical symptomatology. The theories of the pathogeny of œdema regarded generally are three: (1) The purely mechanical theory which attributes œdema to a notable increase of lateral pressure in the capillary vessels—this should be rejected: (2) the view of Hamburger and Heidenhain which considers the formation of lymph as a secretory act of the endothelial cells of the capillary wall and œdema as an exaggeration of this function; (3) the theory of Starling, Winter, Théaulon, which attributes the genesis of the œdema to modifications of the osmotic relations between the liquids situated on either side of the vessel wall and to variations in the permeability of this wall. In regard to the question to be considered two facts are of predominant importance: A. An active simple non-inflammatory hyperæmia of the vessels without hindrance to the flow of the liquid is by itself incapable of producing œdema. B. Lesions of the capillary walls entailing an increase of permeability are an important factor of œdema. For this reason Masius is unable to admit that acute pulmonary œdema has only one pathogeny, clinically it assumes three forms: (1) Inflammatory œdema; here in all probability we have to deal with a reflex vasodilatation, circumscribed or widespread, developed under the influence of some casual factor and followed by a direct lesion of the walls by microbes dwelling in the substance of a normal pulmonary parenchyma—a fact demonstrated by one of Masius's pupils. (2) Stasic œdema, which is by far the most frequent. This is the form met with in affections of the heart, especially initial stenosis, in affections of the vessels—aortitis or arterio-sclerosis—in diseases of the kidney such as primary sclerosis. The experimental studies on the subject have been numerous, but their conclusions are often contradictory and seldom applicable to human pathology. The fact which appears best established is the production of œdema under the influence of an increased pressure in the pulmonary artery dependent on the normal or increased activity of the right ventricle coincidentally with stasis dependent on a paretic or spasmodic inactivity of the left heart. The pathogeny of the œdemas included in this group therefore comprises a great variety of factors. One only among these seems to adapt itself to all cases, and so to constitute the basis of the affection; this is the deterioration of the wall of the capillaries of the lung. Thus in chronic aortitis, in the small red kidney, there is often an extensive arterio-sclerosis and disorders of nutrition which are re-echoed in the osmotic tension of the plasma as well as on the molecular constitution of the vessel walls. Modifications in the permeability of the walls are in Masius's opinion one of the principal causes favouring œdema. On the other hand, many of the affections referred to, especially arterio-sclerosis and sclerous nephritis, react on the left heart and singularly diminish its resistance. To explain the suddenness of the accidents, one must invoke occasional factors such as sometimes irritation of the cardio-pulmonary plexus causing reflexly vasodilatation of the pulmonary vessels; sometimes, on the contrary, sudden paresis or spasm of the left heart coexisting with normal or exaggerated contraction of the right ventricle. C. Toxic œdema, which is known only in the experimental domain. Thus there is an œdema caused by muscarine, the cause of which is a cramp of the left heart, combined with a direct action of the poison on the vessels. Again, there is iodine œdema in the pathogeny of which the last-named factor is probably predominant.

Dr. Teissier holds that there is a definite clinical entity to which the name acute œdema or serous apoplexy of the lung may justly be given. The symptoms are premonitory sensations of tickling in the throat or painful intra-thoracic tension, violent dyspnœa accompanied by spasmodic and continued cough, soon followed by foamy and pinkish expectoration, a true bronchial froth caused by transudation of blood serum with a rain of fine *râles* heard over all the œdematous region. Teissier has come to the conclusion that primary acute œdema of the lung requires for its production a special soil—previous infection (acute articular rheumatism, influenza, the puerperal state, typhoid fever, pneumonia), or intoxication (Bright's disease, and a long way after, alcoholism). Changes in the heart affecting the zones of distribution of the nervous plexuses or ganglions—base of heart, coronary region, left ventricle—must also be given an important place among predisposing causes. The immediate cause of the onset is generally a rapid chill, fatigue, or emotion. Under an influence of this kind, a sudden rise of pressure having been produced in the territory of the pulmonary veins, previous changes in the blood, facilitating serious transudation and concomitant vasomotor disturbances favouring stasis, œdematous fluction will be brought about. As interstitial nephritis presents these various pathogenic conditions in the highest degree, it is not surprising that this form of Bright's disease so often presents as an epiphenomenon the syndrome of acute pulmonary œdema. Teissier has been able to confirm this view of the etiology by experiments. In general terms the gravity of acute pulmonary œdema depends on the degree of renal permeability. In regard to treatment, bleeding, besides relieving the circulation, withdraws a certain amount of toxic substances. Derivatives applied over the nerve trunks and the cardiac plexus are also beneficial. Atropine has not proved of service. Oxycarbonated nitrite of amyl may perhaps be found useful owing to its vasodilator properties and its marked influence on the contractile energy of the heart. Teissier has in serious cases obtained good results from the administration *per rectum* of carbonic acid combined with the use of derivatives and wet cupping. Morphine is a dangerous agent. In desperate cases puncture of the right auricle and tracheotomy with aspiration of the liquid blocking the larger bronchi have been recommended. Teissier has had no experience of these measures.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF SURGERY.

(99) Surgery of the Pancreas.

A discussion on this subject was opened by Professor Andrea Ceccherelli, of Parma, who summarised his conclusions as follows: (1) Surgical operation on the pancreas stands in direct relation with all questions affecting the function of the organ. (2) Wasting, the presence of fat in the fæces, sugar in the urine, bronzing of the skin, jaundice and pain, are the symptoms accompanying the majority of pancreatic affections. (3) Considerable difficulties are met with in complete extirpation owing to the pancreas being deeply situated in intimate relation with other viscera, and being very rich in vessels and nerves. (4) The surgery of the pancreas has not hitherto advanced as it appeared legitimate to hope from the progress of visceral surgery, because very often the diagnosis is difficult, and on that account it is seldom possible to attack the morbid process at its beginning. At present everything tends to show that the surgeon is warranted in operating on the tail of the pancreas rather than its head. (5) It has been proved experimentally that extirpation of the pancreas is possible and compatible with the life of an animal. It has not been proved that the same thing holds good in the sphere of clinical surgery, notwithstanding a few positive cases. This is all the more true that the morbid processes which call for the operation are generally not limited to the pancreas. As a matter of fact one has to do with malignant tumours infiltrating the neighbouring parts, or with adenomata which can be diagnosed only with difficulty. Extirpation is not justified in tuberculous or syphilitic disease. Partial extirpation should be performed in such a manner as to leave one of the two ducts provided the duct of Santorini does not end in a blind sac. (6) The tumours that most frequently develop in the pancreas are cysts. These may be blood cysts, the result of injury or apoplexy; retention cysts, or hydatid cysts. In these intervention is legitimate and useful, but extirpation of the whole organ is not necessary; extirpation of the cyst, if it be possible, or incision being sufficient. In regard to extirpation, one has to consider the question of opening Wirsung's duct, and of the probable escape of the pancreatic juice into the abdominal cavity. In incision of the sac it is prudent, if possible, to stitch the walls of the cyst to the abdominal parietes. (7) In the case of pancreatic calculi the surgeon may usefully intervene for their extraction. (8) An affection which has lately been studied with great care is necrosis of the pancreas. This may call for intervention for the elimination of the fragments of the necrosed organ. (9) In cases of suppurating or gangrenous pancreatitis the rule is not to operate in the acute stage. Later, if there is an abscess, or if the organ is gangrenous, intervention may be useful. Three routes may be chosen: Lumbar, extraperitoneal, transpleural, or median subumbilical. Suppuration must be avoided, but sometimes it is necessary that a portion of infiltrated or necrosed pancreas should be eliminated. (10) In cases of chronic pancreatitis complication may be produced by compression of the bile duct or the pylorus, but in that case the surgeon may usefully operate not on the pancreas but on the liver or the stomach, in order to prevent the interference with function caused by compression. (11) In hernia of the pancreas following wounds reduction and even fixation may be suitable. The thoracic route is preferable if the hernia is diaphragmatic. (12) Intervention may be necessary in contusions and wounds of the pancreas, especially if bleeding occurs. In that case hæmorrhage should be stopped either by suture or by ligature of the bleeding vessels; the clots found in the abdominal cavity should also be removed. (13) Cases of movable pancreas may be observed. Experimental pathology justifies fixation of the organ. (14) In invagination of the pancreas Ceccherelli thinks the surgeon should intervene if complications occur and if elimination is not regularly performed. (15) If as the result of any process the opening of the duct between the pancreas and the duodenum is blocked, a new channel for the pancreatic juice may be made, or if that is not possible a pancreatic fistula may be established. (16) Pancreatic hæmorrhages may occur even without wounds. They depend upon disease of the pancreas most frequently gangrenous. In this case the surgeon should intervene as if the hæmorrhage were traumatic. (17) In "annular" pancreas surgeons have hitherto abstained from operating, but it might be necessary to cut the band or to intervene to remedy the results caused by it on the stomach or intestine. (18) Sutures through the pancreatic parenchyma cause no disorder or change, and are tolerated just as they are in the kidneys, the liver, and the spleen. (19) Wounds of the pancreatic duct may be sutured, but as far as possible in such a fashion that the thread be not in the middle of the duct, in order to avoid the probable formation of concretions. (20) Union of wounds of the pancreas takes place by proliferation of the cells, especially of the connective tissue. (21) It is certain that regeneration of the pancreas takes place. (22) After complete extirpation there is seen a great development of the glands of Galeati, and especially a karyokinetic increase in the epithelium, so that it may be supposed, in accordance with the experiments of Martinotti, that these are capable of adequately replacing the extirpated viscus. (23) The escape of the pancreatic juice into the abdominal cavity does not always cause peritonitis because absorption is rapid. There is reason to believe that, like bile, pancreatic juice is harmless if it is healthy, and hurtful if altered. (24) In extirpation of the pancreas care must always be taken to place ligatures before so as to avoid hæmorrhages and the escape of pancreatic juice. Neither thermo-cautery nor galvano-cautery should be used. They are unsafe, and in such cases the separation of eschars is to be feared; moreover, by radiation they may produce dangerous effects in the neighbouring parts.

Professor Mayo Robson, who presented a report on pancreatic surgery, began by stating that he is convinced that pancreatic affections are much more common that is usually thought. He bases his remarks on his personal experience, he having operated on 40 cases of pancreatic disease and having seen a considerably larger number of cases in which operation was either not consented to or not thought advisable. He dwelt on the importance of posterior drainage where practicable in acute and in suppurative pancreatitis. For reaching the main pancreatic duct he has found it practicable to incise the second part of the duodenum and lay open the termination duct from the papilla. Cancer, of which he has seen over 50 cases, he has found usually to occur after 40, and he believes that the cases occurring earlier in life are, in many cases, chronic interstitial pancreatitis, which may resemble cancer not only in the symptoms but in the naked-eye appearance after death. After describing the symptoms he remarked on the importance of distinguishing between cancer of the head and that of the body and tail of the pancreas. He then discussed the diagnosis, advising that especially in young subjects, but also at times in older patients, a hopeless prognosis should not hastily be given before surgical treatment has been tried, as if the case turns out to be chronic interstitial pancreatitis a cure may result from treatment. He expressed the opinion that excision of the pancreas for cancer can seldom be feasible or justifiable except in those cases where the disease is limited to the body or tail of the organ, and then only when it is caught in an early stage. Of the 15 cases on which he had operated for the relief of symptoms by cholecystotomy or cholecystenterostomy, nine recovered and lived for some time in greater comfort. The important fact, however, that some of the cases operated on and thought at the time to be cancer of the head of the pancreas, but which recovered and are now in perfect health—showing the tumours to have been chronic interstitial pancreatitis and not cancer—has led him to advocate operation in all cases not too far advanced, especially in young or middle-aged patients, not because much good will be done if the case be truly cancer,

but under the hope that the tumour may be inflammatory and not malignant. *Pancreatic Cysts.*—The author has operated on five cases of pancreatic cyst, for which as a routine treatment he advocates incision and drainage, which he has performed in four cases with three recoveries. In one case the cyst was so easily enucleated that it was removed in that way, and the patient made an uninterrupted recovery, but his experience not only in his own cases, but in others seen under the care of his colleagues, would lead him to believe that excision can only rarely be justifiable. In none of his cases were any pathognonomic symptoms present, and the author thinks that the diagnosis must usually be made from the physical signs. *Pancreatitis.*—Mayo Robson draws a parallel between the inflammatory diseases and the liver, such as infective and suppurative cholangitis and chronic interstitial hepatitis and similar diseases of the pancreas and its duct. He believes he has seen functional ailments of the pancreas ending in recovery that would come under the heading of infective catarrh of the pancreatic ducts, and he adduces positive evidence of suppurative catarrh of the ducts, as well as of chronic interstitial inflammation of the gland. He believes that as diagnosis becomes more perfected these diseases will be more frequently recognised and awarded their proper place in medicine. The author assents to the pathological classification proposed by Fitz, of dividing acute pancreatitis into suppurative, hæmorrhagic, and gangrenous pancreatitis; for clinical purposes he considers the subject under acute, subacute, and chronic pancreatitis. In discussing the etiology, he laid stress on bacterial infection as being the essential and immediate cause, but enumerated a number of extrinsic causes such as gastro-duodenal catarrh, injury, and pancreatic and biliary lithiasis. The mode of infection he believes is nearly always through the ducts. Although pancreatitis is a disease without exact pathognomonic signs, the diagnosis can usually be arrived at by a careful study of the history, mode of onset, and the combination of symptoms and signs. A case of acute and infective pancreatitis coming under the author's observation is related, also four cases of the suppurative form which were operated on after abscess had formed; of two in which the pus was evacuated by an incision in the loin, recovery followed, of two opened from the front, both died. In both cases leakage of pus had previously occurred into the stomach and had been vomited. In one case of suppurative pancreatitis in which rupture of the abscess occurred in the bowel, the patient was too ill when seen to bear operation, and gradual recovery occurred without surgical treatment. The treatment of acute infective and frequently that of suppurative pancreatitis practically resolves itself into that of peritonitis commencing in the superior abdominal region, and Mayo Robson lays stress on the getting rid of inflammatory products by lumbar drainage if practicable, although it may be necessary to make the diagnosis by an interior incision. In the acute form he draws a comparison between gangrenous appendicitis and acute infective pancreatitis and considers surgical treatment just as necessary in one as the other as soon as a probable diagnosis can be arrived at. If there be great distension in the epigastrium it will be easier and safer to make the exploratory incision in the left costo-vertebral angle. Treatment other than operative in order to get rid of the distension, relieve pain, fever, and other symptoms until a definite diagnosis can be made was also considered. The details of reaching the abscess when found were also discussed, whether the collection be lumbar, subdiaphragmatic, epigastric or pelvic. *Chronic Interstitial Pancreatitis.*—Professor Mayo Robson lays great stress on the importance of this disease, which he believes is often mistaken for cancer of the head of the pancreas and which he believes has not received much attention either from clinical observers or from pathologists, certainly not as much as it deserves. His experience in this class of cases has resulted from his having operated on a considerable number of cases of jaundice depending on obstruction in the common duct, the obstructive jaundice, wasting, paroxysmal attacks of pain and ague-like seizures having given rise to the suspicion of gall stones, and the absence of relief by medical treatment having rendered surgical treatment necessary. He argues that its recognition is of vital importance, since it is a disease not only capable of relief but of absolute cure by surgical treatment. The author illustrates his assertion by a brief report of 15 cases on which he has operated, with recovery in 14. In the fatal case, operated on when the patient was almost too ill for recovery, a necropsy showed a simple cirrhosis of the head of the pancreas. In another case in which relief was given by cholecystenterostomy, but in which there was a recurrence of the trouble owing to closure of the opening followed by death three months afterwards, a necropsy showed chronic interstitial pancreatitis and not cancer, as the course of events had led those observing the patient to suppose would be found. The author believes that chronic interstitial pancreatitis with inflammation in the pancreatic ducts is a regular accompaniment of gall stones in the common duct, and that it frequently continues after the original cause has passed. This observation has been confirmed by Dr. Ferguson, of Edinburgh, who says that his almost universal experience in cases where death has resulted from infective or suppurative cholangitis is that beads of pus can be expressed from Wirsung's duct. The cases related illustrate the symptoms and the treatment by cholecystotomy, which at once removes tension and allows the pancreatic duct to empty the organ of its infective products. Doubtless at times the manipulation of the head of the pancreas, which occurs during the operation, may detach calculi and inspissated mucus or pus from the pancreatic duct. The simulation of malignant disease of the head of the pancreas by chronic interstitial pancreatitis should lead the surgeon to hesitate in declining operation in any case of distended gall bladder with jaundice, where the patient is able to bear it, as although little good will be done if the disease is malignant, should the disease prove to be inflammatory a real and permanent cure may be brought about. After some remarks on hæmorrhagic pancreatitis, which in the author's experience of 3 cases has always been traumatic, and associated with effusion into the lesser peritoneal sac, he discussed the subject of pancreatic calculi, which form the paucity of specimens in the museums, from the very few examples found *post mortem*, and from the few recorded cases, the author believes must be a rare disease, and usually only recognised by the pancreatitis and the obstruction to the common duct with infective cholangitis to which the calculi give rise. For their removal he recommends exploration of the duct through an opening in the second part of the duodenum, of which operation he gives examples. In conclusion, the author looked forward to the time when pancreatic diseases would be awarded the place they deserved in the diagnostic efforts of the physician, and when the surgeon would be called on much more frequently to treat them at a stage when operation, whether exploratory or curative, might be undertaken with every hope of temporary success or permanent cure.

JULES BOECKEL (Strassburg) said: Operations on the pancreas are indicated in cases of injury, inflammation and its consequences (suppurating, gangrenous or hæmorrhagic pancreatitis, pancreatic necrosis with fatty necrosis), tumours, solid and liquid (cysts). In recent injuries the scope of intervention is very limited, wounds of the pancreas generally proving fatal very quickly from hæmorrhage or concomitant lesions of the neighbouring organs. Of 10 recorded cases death occurred in 8. The only rational treatment is to plug the wound after asepticising it. The search for and ligature of injured vessels, though right in theory, are practically impossible in the great majority of cases on account of the dangerous condition of the wounded person. In inflammations and tumours the surgical procedure is sometimes on the gland itself, sometimes on its more or less immediate neighbourhood. The latter condition is realised when a collection of blood, pus, or other material developed primarily in the pancreas ruptures and becomes encysted between one or other of the numerous peritoneal folds near that organ, or when a solid tumour insinuates itself among the same folds. Under these conditions the operation is extremely simple. The tumour causes a more or less considerable projection, and the serous folds covering it are intimately bound together. One need generally only incise the most project-

ing part of the tumour to lay it bare and then act according to circumstances. On the other hand, when only the gland itself is involved, intervention is more delicate, more laborious, and necessarily limited. It is delicate because the pancreas lies deep, surrounded by numerous and important vessels, the wound or ligature of which may cause fatal accidents. It is limited because only small portions of the pancreas can be extirpated, complete removal inevitably inducing a rapidly fatal form of diabetes. These intrapancreatic operations are indicated in localised tumours and inflammation of the gland. When the affection has been diagnosed—and this is the difficult point, since diseases of the pancreas have no really pathognomonic symptoms—the first thing to be done to lay bare the organ. According to the case it may be reached by three different routes: (1) Subgastric, when, as is seldom the case, the tumour projects above the lesser curvature of the stomach; (2) gastrocolic. This is the procedure of choice; (3) transmesocolic when the tumour has insinuated itself between the folds of the transverse mesocolon. In exceptional cases recourse may be had to incision through the flank (tumours of the tail of the pancreas), the operation then being continued outside the peritoneum. The pancreas having been cleared, search must be made for the focus or the tumour, and then curetting or enucleation should be carried out. Intraglandular operations are of course more dangerous than extraglandular, but even as regards the latter, unless when one has to do with cysts, the prognosis is sufficiently gloomy. The limited statistics at present available prove nevertheless that pancreatic affections which a short time ago were looked upon as incurable may now be dealt with successfully by surgical intervention made at the right time. Thus among 20 cases of suppurating and gangrenous pancreatitis there have been 11 cures and 9 deaths; in 23 cases of hæmorrhagic pancreatitis there have been 5 cures and 18 deaths; in 11 of solid tumours there have been 3 deaths and 8 cures, 4 of which were permanent. Cysts have been operated in 144 cases, which may be subdivided as follows: Operation in one sitting 99 cases, 92 cures, 7 deaths, of which 2 occurred during the operation. Operation in two sittings—16 cases, all cured. Total or partial extirpation—25 cases, 21 cures, 4 deaths. Cases of which no details are forthcoming, 4; 3 cures, 1 death. Extirpation, which is more rarely applicable, is more serious, more troublesome, and often incomplete. It should be attempted only exceptionally when the cyst is movable and a pedicle can easily be formed. In addition to these radical operations, palliative procedures may be practised when phenomena of compression of the bile duct or of the duodenum place the life of the patient in danger, as in tumours and chronic inflammations of the head. The serious risks of these operations and the very slender advantages obtainable from them make it impossible to recommend them. In the case of solid tumours cholecystenterostomy has given in 15 cases 7 speedy deaths and 8 recoveries with a maximum survival of 14 months. As regards cholecysto-gastrostomy (4 cases with very transient improvement), pancreatico-enterostomy (1 case which ended fatally), gastro-enterostomy (2 cases of which 1 died speedily and 1 survived 4 months), they need only be mentioned by way of record. Jejunostomy, recommended recently by Maydl, seems to give better results. The same operations may be performed with success in chronic pancreatitis of the head, which is so often taken for cancer of the organ. They may even be curative rather than palliative when regression of the inflammatory process takes place, which may happen when the lesions are not too old. Cure is then definitive.

(100) Radiography in the Study of Fractures and of Luxations.

G. Maunoury (Chartres), in opening a discussion on this subject, said that the errors that might be committed in the study of the results of radiography were attributable not to the method itself but to defective interpretation. To avoid such errors it was desirable to secure greater precision in the examinations, and to indicate on the prints certain data, notably the point where the vertical line let fall from the focus on to the plate meets the plate. *Fractures.*—Dealing first with simple fractures, the author said that in diagnosis radiography rendered invaluable services by indicating the number, form, and position of the fragments, their over-riding—which, when the proof was clear, corresponded with sufficient exactness to the shortening of the limb—their displacement in different directions, and the situation of splinters. To obtain precise information as to the disposition of a fracture it was necessary to radiograph it at two different angles; generally it was taken from the front (frontal plane) and in profile (sagittal plane). There was no absolute rule about this, and each fracture might require a special position of the tube. Very exceptionally a fracture might escape detection even when the bone was examined in different directions. Stereoscopy also gave valuable information as to the position of fragments. The clinical diagnosis of fractures was as valuable as ever, but radiography complemented it very successfully by making it more definite. It might even give it a character of certitude in cases where the complexity of the lesions or considerable swelling of the soft parts left it doubtful. Lastly, it made it less painful by reducing to a minimum the exploratory manœuvres directed to the seat of fracture. Radiography is useful in all fractures, but especially in fractures of the upper end of the humerus, which are often at the bottom of stiffness and ankylosis attributed to periarthritis; of the lower end of the radius, which are often accompanied by lesions of the carpus; of the leg, and especially those involving the tibio-tarsal articulation in these last radiography alone can give exact information as to the relations of the astragalus, with the tibio-peroneal mortise, a vital point in the prognosis and treatment of these fractures; of the astragalus which a few years ago were wrongly looked upon as being very rare; lastly of the metatarsal bones, which are the anatomical lesion of an affection well known to military surgeons, as to the pathogeny of which there had long been much discussion without its true nature being suspected. The formation of the callus is very interesting if studied with the help of radiography. The first stage cannot be observed, but after some twelve days at the end of the fragments there becomes visible a light clouding which becomes gradually darker. If coaptation of the fragments is perfect the callus forms at the line of the fracture a diffuse globular mass which by degrees becomes transformed into a distinctly limited fusiform sheath incorporated with the compact tissue. If there is slight overriding the cloudy deposit on each fragment forms the medullary canal and constitutes a thick layer where the fragments touch each other at the side. If the overriding is very extensive this lateral interfragmentary callus does not extend the whole depth of the line of contact, but is produced only at the level of one of the fractured ends, which seems to take a predominant part in the work of the bony union. The time taken in the formation of the definitive callus varies, seeming to be larger in proportion to the size of the bone. In certain cases, notably in oblique fractures of the tibia, the callus may remain a long time invisible even when consolidation appears to be complete. Radiography makes visible in the living body all the varieties of callus known to pathological anatomy, and shows how certain kinds of callus may simulate a perfect coaptation of two fragments which are nevertheless very badly reduced. It shows that in the child the work of bony consolidation, instead of, as is the case in the adult, being limited to the immediate neighbourhood of the line of fracture, spreads far along the line of fragments. In treatment radiography enables us better to reduce fractures and to see to what degree such reduction is possible; it is easy to watch the position of the fragments and to rectify it as far as may be necessary during the work of consolidation. When the patient may be regarded as cured, radiography furnishes precise information as to the result. By its means the action of different splints and apparatus—immovable, for continuous extension, etc., can be studied. It has shown that if they are often very effective, they are far from always giving perfect anatomical results: fortunately, perfection of form is not indispensable for the satisfactory restoration of function. Radiography indicates in what cases wiring of the bones may be practised: it is especially in fractures communicating with a joint that this procedure is valuable—for example, in fractures of the elbow and the ankle. In

such cases radiography enables one to see if the relations of the articular surfaces have been sufficiently re-established by reduction. If instead of a recent articular fracture one has to do with an old one, radiography alone can define the position of the bones and their deformities, and indicate what operation may be necessary, in what direction the bones should be divided, what should be removed, etc. It will also guide us in the treatment of faulty and irregular callus. In compound fractures radiography greatly simplifies the operative intervention so frequently indicated, obviating the necessity of groping about for splinters, and in cases where wiring is needed showing how the fragments are to be sawn. In fracture of the joint it shows whether conservative surgery or resection is preferable. In fracture by gunshot it shows the presence of foreign bodies. *Luxations.*—Radiography is much less useful in the case of luxations, although in some cases where a luxation has been overlooked it has shown its existence. But it has so far given no information as to the most frequent causes of irreducibility which lies especially in the soft parts. In old luxations it shows the new-formed bone productions which oppose reduction and reveals the production of false joints. Radiography has enabled us to study and to treat better congenital dislocations of the hip, and it also gives interesting information as to luxations which supervene in coxalgia.

PROFESSOR E. VON BERGMANN, of Berlin, presented a communication on the progress in the treatment of fractures made since the introduction of the Roentgen rays. During the last ten years our knowledge of fractures had made important progress in two particulars: first in regard to the operative treatment of certain simple fractures, with the object of effecting exact coaptation of the fragments; secondly, the diagnosis of the seat of fracture and the pathological anatomy of the bone lesions by means of radioscopy and radiography. There are obvious local causes that hinder the union of fractured surfaces; it is known, for instance, that in a broken femur the interposition of muscular fibres prevents the formation of the callus. Unfortunately, it is not possible with the help of the Roentgen rays to define this with sufficient exactness to warrant an incision. We can only suppose that the case is so if in the image given by the fluorescent screen we see a gap between the bone surfaces separated from each other in the sense of a *dislocatio ad longitudinem*, and this gap always remains equal in the most various positions in which we may place the broken limb. There are, however, other local causes of want of union which are shown clearly by radiography; this is particularly the case in fractures of joints and of small bones. It is sufficient to quote an example, namely, fracture of the patella. Malgaigne had deplored the frequency with which cases of fracture of this bone remained unhealed, and recommended long before the antiseptic era an operative intervention by the application of the hooks known by his name. These hooks, however, are much more dangerous than incision and suture of the fragments with silver or bronze aluminium wire. Examination of fractures of the patella by means of radiography reveals three principal obstacles to union: (1) The inequality in the size of the fragments, the upper being much larger than the lower; they therefore require wiring to keep them in place; (2) the number of the fragments. In addition to the two principal fragments there are small accessory fragments, or small splinters which slip into the line of fracture, and thus prevent accurate coaptation. (3) One of the fragments may be displacement by a movement of rotation in such a manner that the fractured surface of the other fragment meets it at its outer surface, so that contact of the fractured surfaces cannot take place. These various displacements being made visible by radiography, the surgeon is able to make up his mind as to the necessity of an operation, and to search for the seat of fracture, so as to remove the obstacles which have been mentioned, and wire the broken fragments together. Bergmann, in his clinic, has obtained complete bony union in more than twenty-five cases of this kind. The operations proved that the union was bony, and not fibrous, and that the metallic suture cured speedily and permanently. Therefore the operation is the general mode of treatment of fracture of the patella. The question of operation presents itself in a different aspect in the case of other fractures; for instance, when one had to do with a fracture of the lower end of the radius, a subject which has been thoroughly studied by E. Gallois. Whilst the treatment of fractures of the patella is almost uniform, the case is otherwise in respect of fracture of the lower end of the radius, the treatment of which varies according to the seat of the fracture and the displacement of the fragments. Professor v. Bergmann showed a series of photographs taken in his clinic demonstrating the different types of those fractures. Fractures of the tarsal and metatarsal bones were almost entirely unknown before the invention of radioscopy. The symptoms of those fractures were taken for inflammatory swelling or contusion of the foot, and were often treated by massage, with the result that the displacement of the fragments was increased. When the fracture is recognised, it must be treated by complete immobilisation. Illustrations of these fractures were also shown.

---

(101) The Treatment of Infected Wounds. A DISCUSSION on this subject was introduced by Dr. Oscar Bloch, Surgeon-in-Chief to the Royal Frederick Hospital, Copenhagen. He said Lister's antiseptic method (treatment by carbolic acid) was based on the treatment of infected wounds (compound fractures). Although all surgeons were agreed as to the superiority of this method, it was not long before new remedies were sought more efficacious than carbolic acid. The most remarkable outcome of these researches was the replacement of the antiseptic by the aseptic method. All the experiments on various methods of treating wounds were founded on a considerable number of valuable investigations on all questions relating to wounds and their complications—for instance, on microbes and their toxins, on the bactericidal qualities of various remedies, the best method of disinfection, ligature, etc. The author shows that the outcome of all these investigations is that, from a practical point of view, *every wound, without exception, is to be looked upon as infected, and that infection and its complications are due to the retention of secretions containing microbes.* From this it follows that for the efficacious treatment of wounds the surgeon must put before him two objects: To destroy the microbes or their hurtful products, and to prevent the retention of secretions. In other words, antisepsis and drainage must be employed. In order to prevent reinfection of a wound so treated it must be dressed rationally; this is the only way to prevent secondary infection. The author dwelt on the want of agreement and conflicting results of different authorities, and concluded that scientific experiment is incapable of settling the question, what method of treatment is the best for a satisfactory solution of this problem we must have recourse to clinical experience. As the result of his own experience the author holds that *every wound must be treated antiseptically; that carbolic acid is the best antiseptic remedy; that wounds should be drained, and that to dress them in a rational manner an unquestionably sterile dressing must be applied and must be made antiseptic, at least in part, at the moment of application.* Moreover, the dressing must be absorbent, so as to dry up the wound and prevent the surplus of the wound secretions from coming into direct contact with the surrounding air which contains microbes. Lastly, the dressing must be of such a nature as to filter the air which gains admission to the wound and thus purify it from its microbes. Professor Bloch has attained this object by means of dressings of sterilised gauze, carbolised water, and cotton wool. He described in great detail the technique of the dressings which he adopts for different kinds of infected wounds. With regard to internal antiseptics and febrifuge remedies, with a few exceptions he said he placed little reliance on them, and he criticised the value of therapeutic serums, especially anti-streptococcus serum. According to Professor Bloch, it will be well before using these remedies as curative, to wait till experiment has supplied a firmer basis for practice, and a more solidly grounded estimate of the real value of serumtherapy in the treatment of infected wounds.

(*To be continued.*)

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF SURGERY.

[*Continued from p. 28.*]

(101) The Treatment of Infected Wounds.

M. Felix Lejars (Paris) said that in recent years the treatment of infected wounds had formed the subject of numerous experimental and bacteriological researches. They had yielded valuable information but all required to be controlled by observation. For the profitable study of the problem, which is very complex, it must be considered under two heads: (1) Recent infected wounds in which the infection has not yet expressed itself in local or general reactions. These might perhaps be better designated recent wounds assumed to be infected. This assumption, however, should in practice be extended to every accidental wound, and bacteriological examinations show that it is well founded. It is known that even operation wounds are far from being amicrobic. On the other hand, there are no means of recognising in a recent wound by what microbes it is contaminated, what is their virulence, and what their ultimate effect. It has been proved that neither the look nor the visible course of traumatic foci are in this respect sufficient guides. *Therefore, every accidental wound should be treated as infected.* But how is it to be treated? It is known that the absorption of virus through the injured surface is almost immediate; the rapidity of absorption, however, varies with different microbes; moreover, the dose increases with the duration of impregnation. From this may be drawn the conclusion that the cleansing of the wound, in order to be efficacious, should be as early as possible, but whenever it is done it will be useful. Experience has shown (*a*) that we are powerless to destroy all the germs in a traumatic focus; (*b*) that the natural defensive power of living tissues plays a preponderant part in the fight against infection. The very first procedure, therefore, is mechanical cleansing, which should be minute and complete, aided if necessary by enlargement of the wound and removal of dead tissue. Care should, however, be taken to respect the integrity of living cells, which should be helped in their defensive reactions, nothing more. Sterile water, artificial serum, sterilised boiled compresses entirely answer these requirements; it is not the nature of the fluid used but the method of its employment that gives practical results. Hurtful in large doses, antiseptic solutions, when diluted sufficiently not to alter the living cells, have really no other useful effect than mechanical cleansing. Physical conditions of the same order have to be fulfilled by the dressing. It must be aseptic, absorbent, protective and immobilising, in a degree applicable to the different regions and for a variable period. (2) Infected wounds, the infection of which is expressed by more or less pronounced reactions local and general. Here, also, two conditions have to be distinguished: (*a*) the clinical signs of infection may be of recent date and the wound is not suppurating; (*b*) the wound is in active suppuration. In either case specific serumtherapy is indicated; this Lejars considers the scientific, natural method, and the method of the future. Unfortunately as yet only antitetanus and antistreptococcus serum are available. The former is only efficacious as a preventive, while the latter has mostly been used in puerperal fever and erysipelas. Against other microbic infections of wounds we have as yet no effective serum, and against associated infections we are powerless. This makes the treatment of the local focus all the more necessary, and, as in dealing with cases belonging to the first category, the surgeon has to set before him a twofold object. The first thing to be done is to cleanse the whole surface of the wound; then it should be dressed so as to favour exosmosis, continuous drainage of the whole surface, and prevent all stagnation and superadded infection. The object of the cleansing is especially mechanical, while that of the dressing is especially physical. If these conditions are thoroughly fulfilled the surgeon will have, as far as is possible, protected the living cells against the attack of septic agents without hindering their defensive reactions. In dealing with a suppurating wound the same principles must be applied—thorough exposure of the suppurating focus, and complete and continuous drainage. In certain putrid and gangrenous forms, and in burrowing wounds, oxygenated water, which appears to have a powerful effect on anaërobic microbes, is most useful. (3) Infected wounds with grave general infection — traumatic septicæmia. Here also it is to specific serumtherapy that we must look for rational treatment, but its action is much less certain than in the early stages of infection. At present only experiments can be recorded, and even antistreptococcus serum has seldom been used in traumatic septicæmia. Lejars thinks that it deserves to be tried on a more extensive scale in large doses. In the meantime we must use local treatment preceded by thorough cleansing of the focus. On the other hand, artificial serumtherapy, by restoring the blood pressure and stimulating diuresis, increases the natural defence and vital resistance of the organism.

(102) Intestinal and Gastro-Intestinal Anastomoses.

Dr. Roux (Lausanne) opened a discussion on this subject. He said experiments on dogs did not give a faithful picture of what was observed in man, whose digestive canal presented a material more manageable and less untrustworthy. Anastomosis had for its object the turning aside of the course of the food whether on account of the dangers or inconvenience caused by its presence or its passage over certain points of the gastro-intestinal canal or on account of one or more obstacles which it would be impossible, dangerous, or inopportune to remove. It is a procedure palliative in appearance, but has often a curative effect. In regard to risk, technique and results it stands midway between fistulæ (jejunal fistulæ, enterostomy, and preternatural anus) and radical operation (pylorectomy, excision of tumours or diseased loops). Anastomosis is effected by lateral apposition. It is the most practical of intestinal unions (*a*) because it requires less strict precision, (*b*) because it allows a larger junction without risk of forming a diaphragm or valve, (*c*) because it allows an opening of unlimited length which is less subject to later contraction, (*d*) because it is independent of the calibre of the tubes to be united. It is also the procedure most within reach of all operators. Entero-Anastomosis.—*Acute Affections.* Anastomosis is contra-indicated: (1) When the state of the patient does not allow more than enterotomy. (2) When the state of the intestine demands, under penalty of death, the immediate removal of one or more loops; nevertheless it may be combined in some cases with extraperitonealisation of these loops (for instance, strangulated hernia). (3) When the state of the patient and that of the intestine together with the skill of the operator allow something better to be done. Anastomosis is indicated: (1) When the re-establishment of a channel for the fæces is alone in question, especially if a more radical operation appears to be too long or too dangerous. (2) Even after the success of a disinvagination or untwisting, if fear is entertained for the peristaltic function. *Chronic Affections.* — A. Anastomosis should be preferred in cases where there are numerous adhesions, where it offers a better chance, leaving out of account the nature of the disease. B. It should be the operation always chosen: (1) In cases of inoperable tumours. (2) In presence of certain complex, multiple, inaccessible inflammatory foci (tuberculosis with burrowing, actinomycosis). C. Recourse should be had to anastomosis as a preliminary operation: (1) In cases of operable tumours in very debilitated patients (for instance in commencing occlusion): (2) In cases of inflammatory affections with deep burrowing, external pyostercoral or genital fistulæ, etc., which are often cured by this first intervention if care has been taken to combine anastomosis with unilateral exclusion, a procedure which only takes two or three minutes, and which is suitable for all cases of classes B. and C. Life is compatible with 1 metre 50 centimetres of jejunum and the half of the colon, the rest being excluded. The surgeon therefore need not be afraid to operate on healthy loops at a distance from the focus of disease. Gastro-intestinal Anastomosis Gastro-enterostomy, as being less dangerous, should precede

pylorectomy as a preliminary operation when the condition of the patient makes it desirable. It may replace it if the tumour is inoperable. It should always complete it (Billroth's second method) so as to give the patient at once the benefit of the radical and of the palliative operation when recurrence takes place, by making a new pylorus at as great a distance as possible from the old one. In non-cancerous affections of the pylorus and the stomach, for which an easier evacuation of the gastric contents is desirable, gastro-enterostomy should be preferred to pylorectomy and pyloroplasty, because it is easier and equally efficacious whether in its ordinary form or as duodemostomy. Gastro-anastomosis is very much superior to gastroplicatio and gastropexy; if done by the Y method it is an ideal operation. For the surgeon who is equally handy with the seamstress's needle and with the more or less automatic approximation apparatus, suture will remain the method of election, because it alone gives reunion of the mucous membrane by first intention, and because it allows easy post-operative treatment, an important matter in all cases. Murphy's button, the best thing of the kind, should be reserved for cases — and they are too numerous—where minutes have to be counted. It gives unlooked for results. In all these operations a surprising proportion of deaths from pneumonia takes place; these are not sufficiently explained by the necrosis.

DR. SOULIGOUX (Paris) said: Intestinal anastomosis constitutes most frequently the principal operation in the treatment of cancer and of stricture of the intestine; or the operation may be complementary. In presence of a case of acute or even chronic intestinal obstruction, intestinal anastomosis must yield precedence to preternatural anus, even if one has to intervene by a secondary procedure later. In case of retardation in the flow of fæces without obstruction, if the surgeon finds himself in presence of a movable tumour which can easily be taken away, it is enterectomy that should be practised; but the operation should be completed by anastomosis, either lateral or termino-lateral, operations which are more simple, more rapid, and more certain than circular enterorrhaphy. If the tumour is adherent, and its removal greatly complicates intervention, anastomosis is the only operation to be performed. It is of slight gravity, and, although only palliative, gives a fairly considerable survival. In cases of stricture or cancer of the cæcum, it should consist of turning of the ileum into the sigmoid flexure, and in the rest of the large intestine of a junction of the parts of the colon situated above and below the obstacle. In the case of strangulated hernia it may be either a preparatory or a definitive operation, much simpler and more certain than a circular enterorrhaphy. Souligoux summarised his conclusions as follows. The stomach has become an organ essentially belonging to surgery. Only dyspepsia of nervous origin lies outside the sphere of intervention. In cases of cicatricial stenosis of the pylorus or of the first part of the duodenum, gastro-entero-anastomosis is the operation of choice; indeed the only one admissible since it is almost free from danger, it provides against all accidents, and thanks to it, patients recover flourishing health. Moreover, it is less serious and more sure than pylorectomy or gastroplasty. In cases of stenosis of cancerous origin it is also gastro-entero-anastomosis that in the present state of opinion both of medical men and of patients will be most frequently employed. Pylorectomy is to be preferred to it only in cases of commencing cancer, without adhesions to the liver, pancreas, or colon, without involvement of the preaortic, pancreatic, and hepatic glands, and of course when there is no trace of generalisation; in a word, when it is easier of performance, and provided the surgeon adopts the technique recommended by Hartmann and Cunéo. Gastro-entero-anastomosis will most frequently be the necessary complement of pylorectomy when extensive resections of the stomach and duodenum have been performed. In the case of gastric ulcer in process of evolution gastro-jejunal anastomosis will still be useful, not to stop hæmorrhage, but to place the organ in a state of repose, and to allow cicatrisation of the lesion to take place. In bilocular stomach of cicatricial origin gastro-entero-anastomosis is the operation of choice; it is much superior to gastroplasty. In cases of dyspepsia when no improvement has been brought about by medical treatment, when phenomena of retention of food with violent pains causing contraction of the pylorus persist, it will be the operation of necessity. Done early it is not very serious, and allows the stomach to get well by establishing a means of escape for the gastric contents. Von Hacker's method is much the best when it is feasible. The anterior route should be followed only when it is impossible to perform posterior anastomosis. The operation which is physiologically the most complete is that of Roux. Nevertheless the posterior route, which provides against most of the accidents of circulus vitiosus, appears preferable to Souligoux. Whether carried out with the help of suture, of anastomotic buttons, or of crushing as he has recommended, it is the most rapid and therefore the less dangerous. In cases where phenomena of obstruction by adhesion may occur, one should not hesitate to perform a secondary jejuno-jejunal anastomosis as Ricard himself and many others have done.

---

(103) Exploratory Operations on the Stomach.

MR. A. ERNEST MAYLARD (Glasgow) presented a communication on this subject. He said its object was threefold: (1) To indicate those conditions for which the operation of early exploration is of special value; (2) to make clear the safety and simplicity of the operation; and (3) to demonstrate the best method of performing it. With regard to the first point, early direct digital examination with visual inspection would, in obscure cases, determine whether the disease was innocent or malignant. If the former, the appropriate treatment would be suggested, and the patient's mind relieved of all doubts and fears, so distressing and harmful in their indirect effects; while, in the latter, the growth might be removed at such an early period of its development that its eradication might prove complete and permanent. With regard to the second point—the extreme safety and simplicity of the operation—the greatest encouragement may be held out to the patient to submit to the operation. When no harm can follow even if no practical result can be obtained, there need be no hesitation on the part of the practitioner in advising the operation, and none on the part of the patient in submitting to it. The third point concerns the operation itself. Upon the thoroughness with which this is executed to a large extent may depend the value of the procedure. The steps of the operation, including the fore and after-treatment, are as follows: (1) *Preparation of the Patient.*—Lavage is practised for two days previously; the diet is simple; the bowels are well emptied. A nutrient enema and a subcutaneous injection of liquor strychninæ are given just prior to operation. (2) *Abdominal Incision.*—In most cases the median incision above the umbilicus is sufficient. In some cases, however, the left oblique (Fenger's) is necessary. (3) *External Examination of the Stomach.*—The mobility of the organ is first noted to determine the presence or otherwise of adhesions. The anterior surface is palpated, and the posterior, by tearing to the required extent, through the gastro-colic omentum. Bidigital palpation should also be practised. (4) *Internal Examination of the Stomach.*—This is effected, first, by direct inspection, and, secondly, by digital exploration. To render inspection efficient, the stomach must be completely cleared of its contents through an incision in its anterior walls. This is effected by a specially-devised siphon apparatus. Fluid is introduced as required, and withdrawn until the cavity of the organ is perfectly clean. All proper protective measures are taken o guard against infection of the peritoneal cavity. As soon as all fluid is withdrawn the speculum is introduced. The specula employed are of special sizes. They resemble the ordinary large size glass-reflecting vaginal specula (Fergusson's), only are much longer, and cut both obliquely and transversely at their ends. By means of these, and either direct daylight or reflected artificial light, a perfect visual inspection of the mucous membrane is obtained. Digital exploration follows visual, and is executed by the index finger of the right hand, coupled with, if necessary, the external manipulation of the stomach with the fingers of the left hand. (5) *After-treatment.*—The gastrotomy wound is closed by a continuous Lembert, and the abdominal incision united in three separate layers. The patient is fed for

the first forty-eight hours by nutrient enemata. Of various illustrative cases cited the following is a good example:—A lady had suffered for years from dyspepsia. Various medical opinions had been expressed, and the commonest conception of her troubles was that they were due to antecedent ulceration. She was much depressed by the various opinions expressed as to the cause of her complaint, and the more or less apparently useless effects of the innumerable drugs administered. An exploratory operation revealed a chronic gastric catarrh. So far as the operation itself was concerned the patient suffered not the slightest ill-effects, while the result mentally upon the patient was of the very best. To her all doubts in her case were settled, and, aside altogether from the use of appropriate drugs and suitable food, the beneficial effect of the mind upon the body seemed to have most to do with her comparatively rapid and complete recovery.

(104) Gastro-enterostomy.

Dr. A. Monprofit (Angiers) presented a communication on gastro-enterostomy, which, he said, at first used solely in the treatment of inoperable tumours of the pylorus, may also be employed as a palliative in malignant tumours of the stomach not involving the pylorus. Such patients are relieved and their life is prolonged. Gastro-enterostomy and gastrotomy should not be opposed to each other, but an endeavour should rather be made clearly to determine the limits where one and the other of them stop. There is at the present day less tendency to remove, at the cost of considerable mutilations, large extensive and adherent tumours. These cases derive much more benefit from gastro-enterostomy. On the other hand, limited small movable tumours of the pylorus can be removed with excellent results. The procedures that have been successively used have been anterior gastro-enterostomy by Wölfler's method, which does not always give good results; then the methods most employed are those of von Hacker and Roux. The procedures of apposition by means of Murphy's button or by the method of Souligoux have each their partisans. Monprofit has always employed sutures with excellent results. He does not produce coprostasis, but contents himself with carefully protecting the abdominal cavity. When the stomach is much distended with liquids, he empties it by means of an india-rubber tube introduced through a puncture made in the mucous membrane before complete incision. Following the example of Roux, he feeds his patients as early as possible, giving them first liquid, then solid food within the first few days.

Dr. Bourget, Professor of Clinical Medicine in the Cantonal Hospital, Lausanne, read a paper based on 100 cases of stricture of the pylorus, in 46 of which gastro-enterostomy had been performed. The communication was presented to the Section of Medicine, but an abstract of it may conveniently find a place here. His conclusions may be summarised as follows: (1) Gastro-enterostomy is required whenever the calibre of the pylorus is insufficient to allow the free passage of food from the stomach into the intestine. (2) To warrant the performance of the operation the cause of the stricture must be permanent or definitive in character either tumour band, cicatrised ulcer, or fibrous ring. (3) It is contraindicated in cases of temporary narrowing of the pylorus, as by pyloric spasm in neurasthenic persons, and in gastric stasis from ptosis or atony of the walls. (4) It should be done only after a careful study of the mechanical working of the stomach, which should be examined in different stages of digestion by means of test meals, these being strictly the same for each examination. In cases where a transient cause of stricture (neurosis) is suspected similar explorations should be made, but should be repeated more frequently on account of the variability in the results. The effect of a prolonged tepid bath, bromide of potassium and even suggestion should be tried. (5) Insufflation of the stomach is necessary to obtain information as to cases of gastric ptosis or as to the importance of the dilatation. (6) Gastro-enterostomy is a curative operation in cases of pyloric stricture from cicatrised round ulcer, fibrous ring, or peri-pyloric adhesions. (7) It is palliative in cases of malignant tumours involving the pylorus, but it may prolong the life of the patient to an altogether remarkable extent. (8) The results of the operation have not been satisfactory in neurotic patients or in those who are the subjects of ptosis. (9) After the operation the chemical function of the stomach is but slightly influenced, although the standard of acidity is lowered. (10) The mechanical work of the stomach is considerably modified. The evacuation of the gastric contents is ensured; it is performed in a normal and rhymical manner as if it were regulated by a normal pylorus. The duration of work of gastric digestion in a patient who has been operated on (after healing of the surgical wound) is the same as in the normal individual. (11) The stomach gradually regains its normal size and position.

(105) Transplantation of the Tendons in Treatment of Paralysis.

Dr. Oscar Vulpius, *Privat-docent* of Surgery at Heidelberg, read a paper on this subject. He said that the transplantation of tendons had come into use only in recent years, although the idea of replacing the action of paralysed muscles by that of healthy muscles was sufficiently obvious, the procedure not very difficult, the danger infinitesimal, the results good, and the occasion of operating frequent. He based his communication on 160 operations done in his clinic. Thanks to the most rigorous asepsis, including the use of gloves and a mask, he had had a series of 130 transplantations without any trace of infection. He prefers what he calls the "descending" method; he sacrifices no muscle, but brings the distal end of the divided tendon into connection with the neighbouring muscles. In this way he benefits the paralysed muscles without damaging the healthy muscles which are to replace them. The most important indications for the operation are: Destruction of muscles, tendons, and nerves by injury and spinal paralyses, foremost among them being infantile spinal paralysis. In partial paralysis the operation is distinctly indicated; in total paralysis the surgeon must choose between it and arthrodesis. Transplantation has shown that total paralysis is in truth more rare than is believed. As regards results, success should be instantaneous in this sense that, at the end of the operation, a normal position of the articulation should have been obtained. Vulpius's 160 operations have shown that this improvement of position is permanent and that it is followed by a return of more or less normal mobility. The success is sometimes increased to a surprising extent under the influence of post-operative treatment. The more circumscribed the paralysed territory, and the nearer healthy muscles having a similar function are to be found, the more brilliant will be the success of the operation. In spastic paralyses success consists not only in correction of the attitude but in disappearance of the spasm. The results also depend on the localisation of a paralysis. The most favourable part for the operation is the leg, the thigh is less so; the musculature of the fore-arm presents greater difficulties, although Vulpius has had some very satisfactory results. Complete failures are very rare if there has been no defect in technique. Relapses have become much more rare as experience has increased, and in such cases a second operation may correct the first. On the whole Vulpius thinks himself justified in warmly recommending transplantation of tendons in the treatment of paralysis. A rational combination of the various modern methods may at least make life worth living for thousands of poor paralysed sufferers.

(106) Surgical Treatment of Hydatid Cysts of the Liver.

Professor Thomas Jonnesco (Bucharest) said that at the present time four kinds of operations are performed for hydatid cysts of the liver: (1) Puncture, whether followed or not by parasiticide injections; (2) marsupialisation; (3) incision followed by evacuation and suture of the cyst; and (4) enucleation and extirpation of the cyst. The last operation, which is ideal, is so rarely applicable that it can hardly be taken into account unless as an exceptional intervention. Puncture should be given up as uncertain and even dangerous. Marsupialisation, in view of the duration of the treatment, remains an operation of necessity applicable to suppurating cysts, and to those in which the calcified adventitia no longer allows retraction of the pouch to take place. The operation of choice consists in incision of the cyst, which is

emptied of its liquid contents, daughter cysts and germinal membrane, and suture; the pouch is left without drainage or fixation of the cyst to the abdominal wall. Jonnesco has operated in 6 cases of cysts varying in size from that of a man's fist to a diameter of 20 or 30 centimetres, and always with success. The effusion of bile into the cyst is not a contraindication. He has cured one case of this kind. In a woman operated on by him he was able in the course of a second intervention for a fresh cyst to observe the result of the first operation two years afterwards. The pouch had completely disappeared, and in its place there remained only a hard cicatrix adherent to the under surface of the liver.

(107) Anæsthesia by Subarachnoid Injections of Cocaine in the Lumbar Region.

Dr. Severeanu (Bucharest) said he had induced surgical anæsthesia about 70 times by injecting hydrochlorate of cocaine into the spinal canal. This method seems to him to have certain drawbacks which he considers it important to point out. The amount of cocaine which he used varied from 1 to 4 centigrams. In all the cases he observed a general weakness lasting one or two days, and sometimes causing great anxiety, There was very frequent vomiting, with headache, which was generally very severe. Independently of the dangers of the use of cocaine, he finds there is a very serious inconvenience attaching to this particular procedure—namely, that it allows the patient to witness the operation.—M. Tuffier said he had performed 125 operations, among them 58 laparotomies, after cocaine anæsthesia by Bier's method. The phenomena which follow the injection are nausea, which may go on to vomiting when too large a dose has been injected; pallor of the face, respiratory distress, increase in the frequency of the pulse on the day after the anæsthesia; there may also be some vomiting, and more or less violent headache lasting fifteen to twenty-four hours is practically always observed. Of the 125 patients operated on, 5 died; in 4 of these the method of anæsthesia could not be held responsible for the result. The other patient died on the very day of the operation. *Post-mortem* examination showed the existence of a heart lesion complicated with pathological condition of the lung, and M. Tuffier thinks that in that case too the injection of cocaine had nothing to do with the death.—M. V. Nicoletti (Naples) said he had been able to show by numerous experiments on the rabbit and the dog that there is no histopathological lesion of the nervous system following subarachnoid injections of cocaine in the lumbar region. This appears to warrant the inference that the anæsthetic property of cocaine results solely from its action on the vascular system of the spinal cord. He has been able to produce anæsthetic effects in animals by subarachnoid injections not only of cocaine, but of ergotin, antipyrin, and quinine.—M. Racoviceanu-Pitesci (Bucharest) said that, like M. Tuffier, he had operated on 125 patients after anæsthesia by Bier's method, using doses varying from 1 to 4 centigrams. In 80 cases he noticed symptoms of slight intoxication which sometimes lasted four and even five days. In 3 patients the symptoms were so severe as to necessitate artificial respiration and subcutaneous injections of ether. He further stated that he knew of 2 cases in Roumania in which death had followed cocaine anæsthesia produced by injection in the lumbar region. He does not think, therefore, that this method can replace chloroform anæsthesia.

(108) Pericardotomy through the Thoracic Insertion of the Rectus Abdominis.

Dr. A. Voïnitch-Sianojentzky presented a communication on this subject, in which he said that pericardotomy by a single longitudinal incision through the thoracic insertion of the rectus abdominis is a perfectly simple procedure. The incision corresponding exactly to the anatomical axis of the anterior mediastinum makes it possible to penetrate the pericardium without touching the pleura, and this can be done with perfect certainty, whatever may be the size of the pericardial effusion. This procedure should always be preferred for cases of small pericardial effusions, or when it is impossible to diagnose the size of the effusion. The longitudinal incision can be enlarged without difficulty downwards to the bottom of the pericardium as soon as that has been laid bare; in consequence of this the best drainage can always be obtained. The tubercle of the left sixth chondro-sternal articulation is a landmark in the incision and in the puncture of the pericardium.

---

(109) Surgery of Cancer.

M. J. L. Faure (Paris) holds that cancer is a local disease which can be cured by a local operation. It is necessary that the operation should be complete, going far beyond the limits of the disease. Every incomplete operation is invariably followed by recurrence or rather continuation of the disease, for "cancer does not recur, it continues." While removing the disease, therefore, the surgeon should take no heed of how the breach is to be filled up—the wound must be dealt with afterwards as may be possible. Taking these principles as his guide, M. Faure has during the last five years operated on a considerable number of cancers in all regions—face, tongue, jaw, pharynx and larynx, thyroid body and glands of the neck, branchial remnants, stomach and intestine, testicle, ovary, breast, uterus, and rectum, scapula, femur and ilium. He groups together all kinds of malignant tumours, whether epithelioma or sarcoma, as he holds that the same rules should apply to both these affections. He does not include in his statistics any case dating from less than a year back. Under the conditions defined he has had 93 cases of cancer in every situation and of every degree of gravity. In 18 no recurrence occurred within a space of time varying from 12 to 47 months. Of these 2 who had had extensive epithelioma of the upper jaw and of the floor of the mouth died, after 24 and 40 months respectively, of an intercurrent malady without sign of relapse. This gives in round numbers 20 per cent. of cures. Faure admits that the period mentioned is not sufficiently long to justify him in speaking of definitive cure, although he has never seen, at least in external cancers, recurrence take place after a year of apparent cure; but 14 of his patients, or 15.05 per cent. of the whole number who were discharged from the hospital cured, have disappeared and cannot be heard of, and Faure assumes that among them there have been some other instances of prolonged freedom from recurrence. He regards his statistics of 20 per cent. of cures, which include favourable, moderately favourable, and extremely unfavourable cases, as "truly consoling," and as enforcing the conclusion that it is wrong to despair of curing cancer and that we have the right, and should consider it a duty, when confronted with that disease to "undertake everything and dare everything."

---

(110) Cancer of the Cheek.

M. Morestin (Paris) said that 12 patients suffering from primary cancer of the cheek had come under his observation. Of these 1 was a woman and 10 of the 11 men were smokers, while the eleventh, who did not smoke, chewed. All had very bad teeth, and some had leucoplasic patches in the immediate neighbourhood of the tumour or on the opposite cheek. In 10 of the 12 cases the growth started in the immediate neighbourhood of the lower gingivo-genial *cul-de-sac*, extending afterwards on the one hand to the internal surface of the cheek, and on the other invading the mucous membrane of the alveolar portion of the jaw. The glands became enlarged early, they became fused with each other and with the submaxillary gland and soon became adherent to the jaw. The upper gingivo-genial *cul de sac* is not involved, and below it there remains a band of healthy mucous membrane. The floor of the mouth, too, generally remains intact for a fairly long time. The prognosis of cancer of the cheek is always very grave, its evolution takes place in a few months, and it soon gets beyond surgical treatment. In the cases in which intervention is possible the most general plan will be to remove *en bloc* the tumour of the cheek, the submaxillary glandular mass, and the corresponding part of the maxillary bone. Of the 12 cases reported by M. Morestin, 7 were inoperable. In the other 5 he operated, and one of the patients, who was absolutely cachetic, died the same day. The other 4 bore the operation well, in 3 relapse occurred, death occurring in from three to eight months; the fourth was lost sight of.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF GYNÆCOLOGY.

(111) Treatment of Cancer of the Uterus. Dr. Gustave Richelot (Paris) introduced a discussion on this subject. Dealing first with vaginal hysterectomy, he said total extirpation of the uterus through the vagina is a *rational* method, whilst division of the cervix such as used to be done formerly allowed the infiltration, which had made its way through the isthmus and reached the uterine mucous membrane, to persist, and sections, even when done early, on histological examination showed between the muscular layers cancer cells divided by the bistoury, the rest of which had been left in the stump. By total extirpation we remove all those causes of immediate recurrence. Richelot has a series of 100 operations with 6 deaths. In the eyes of every man who studies his own observations rather than figures which cannot be controlled or analysed the few cases of failure occurring in consequence of incomplete diagnosis and exceptional difficulties fade into insignificance before the marvellous simplicity and almost certain success of all operations performed on definitely circumscribed tumours and movable uteri; and these are, after all, the only cases in which one can count on getting satisfactory results. Again, vaginal hysterectomy has proved *efficacious*, having given prolonged survivals and survivals without recurrence. The author calls special attention to the absence of recurrence up to the date of his report. Ott, of St. Petersburg, has had cures maintained after 12, 11, 10, 8, and 6 years; Landau after 9½, 8, 7, 6, 5, and 4 years; Le Dentu and Pozzi after 6 years; Quénu, Terrier, and Hartmann after 5 years. Olshausen, Fritsch, and Lauwers have had similar successes. Richelot's results at the date of his report were as follows. In 1894 he had two old cases in which a cure had been maintained for 7 and 6 years respectively. One of them lived 12 years, and died of cerebral hæmorrhage; the second is still alive and well 12½ years after the operation. Other cases with which he still keeps in touch have remained well for 10, 9, 8, 6, 4, 3, 2¾, and 2½ years. More recent cases are left out of account. Others he has lost sight of who had remained well 5, 4½, 4, 3½, and 3½. Among those patients who have so distinctly benefited by intervention there was one in whom the cervix was much ulcerated, almost destroyed, the uterus, however, being perfectly movable; another with a cervix much shortened and excavated; another with a cervix friable and much infiltrated, and another with the posterior *cul-de-sac* slightly invaded. Some authors manifestly exaggerate when they speak of definitive cure after the completion of 3 years. Richelot refrains from using that word even after 5 years and more, although he is strongly tempted to regard cases which remain well for 9, 10, and 12 years as definitively cured. But to deny prolonged cures and the good results of vaginal hysterectomy in cases of typical cancer, clearly shown to be such by their clinical course and microscopic structure, is to shut one's eyes to evidence. And since among his 100 cases he is able to point to at least 18 in which the operathoroughly beneficial, of whom many appear to be definitively cured, he thinks himself justified in saying that his anticipations were well founded, and that those only can say that they are disillusioned who have dreamt of an impossible degree of success. Passing to the consideration of abdominal hysterectomy, Richelot said the distinct improvements in technique had again brought the high operation into favour, and many surgeons are induced to practise it without sufficient criticism. He absolutely condemns surgeons who attack spreading cancers with the pretence of "removing everything," and do not hesitate to resect the broad ligaments, to burrow through infiltrations and neoplastic fragments, and to follow glands up to the aorta. One must adopt the same principles as for all cancers, namely, to intervene at the earliest possible moment and to remove not only the primary tumour but the corresponding lymphatic zone and glands. Looked at in this way the abdominal method is applicable particularly to cases in which there is no propagation appreciable clinically. But to insist always on the "emptying of the pelvis" in the simplest operations appears to Richelot an exaggeration. There have been cases of hysterectomy in which there has been no search for glands and which have yet given very prolonged survivals. That search is often uncertain and illusory; besides the glands, there is the infected zone of vaginal wall and parametrium and the invisible tracts through the tissues. The slightest reflection and observation make it difficult to understand how surgeons can dream of the complete dissection of infected tissues. The comparison with cancer of the breast is misleading. The axillary glands are united in a bundle and buried in a mass of fat, which is easily detached, and in order to destroy all the tissues and all the lymphatic vessels between the tumour and the group of glands it is permissible to cut wide and deep and to take away in one mass, skin, fat aponeurosis and even muscles, without having any organs to be careful about or dangers to encounter. But what is to be done in the pelvic cavity? What signifies the opening up of the broad ligament as if we could scrape its two folds and the laying bare of the ureter as if we could really strip it, destroy the last connective mesh and follow the cancer cells along the iliac arteries? The glands are only resting places in the path of infection; what is the use of removing some of them? For these reasons Richelot holds that the pursuit of the cancerous invasion through the pelvis is an illusion. After making praiseworthy efforts to show that this method is capable of giving longer survivals and more frequent radical cures, writers give as examples only cases of women who have died or are about to die or too recent to supply grounds for any conclusion. Discussing the relative value of the two methods Richelot said cancer is primary local and infects secondarily. Many authors have adopted the parasitic theory, but the soundest investigators have shown that in spite of certain rough analogies the hypothesis of a microbic etiology is improbable. Richelot is disposed to think that epithelioma, however local may be its origin, is a disorder of nutrition not dependent on external causes. One proof among others is heredity, the influence of which is manifest; another is the link connecting cancer with arthritis. A hundred times he has seen cancer and arthritic disease transmit each other, alternate with each other, and coincide in such a fashion that to his mind it would require a very rooted scepticism to exclude malignant tumour from a pathological family where it so naturally finds a place. It is just in this mysterious and varying action of the economy which regulates the degree of cellular anarchy, modifies its evolution, and determines the prognosis that we must learn to see things as they are. It is this that gives us means of combating the disease while at the same time marking out limits which cannot be passed. The variability of cancers of the uterus is well known. Most striking is the different course which in women of equal age and without apparent reason two cancers similar in structure and situated in the same region may run. Another remarkable and well-known fact is the more favourable prognosis of cancers of the body. They last for years, and remain much longer circumscribed and operable. Why? The anatomy of the uterine mucous membrane and wall and the arrangement of the lymphatics do not tell us how it happens that the uterus, profoundly degenerated on its inner surface and reduced to a thin shell, is not always surrounded by a zone of cancer and infected glands. In short it is known that uterine cancer passes through two periods: that it remains shut up in the uterus before invading the neighbouring regions, and that the duration of those two periods is subject to unknown conditions, among which doubtless is the influence of the "morbid temperament." This being the case what is our object and what can be our pretension? The end dreamt of is to intervene during the first period before the smallest cancer cell has escaped from the uterus. We can do this by

operating soon after the commencement. We can also do so a little later if we chance to meet with a cancer of slow course. What, then, will happen? Having left no trace of diseased tissue we have nothing to fear from our usual enemy, recurrence by simple continuation, and we come very near to obtaining a radical cure. We should, in fact, get it, but for the possibility of a constitutional predisposition, which may not be exhausted, and may produce a new cancer after a longer or shorter space of time. This, however, is only a contingency, and for this reason, whilst admitting the instability of our victories, it is permissible to believe in definitive success. Such, said Richelot, was the idea that inspired him fifteen years ago—to prevent invasion, not to pursue it; and such he still holds to-day is the true treatment of uterine cancer. Outside that all is precarious, uncertain, or foredoomed to failure. Nevertheless, the accommodating organism still comes to our aid. Intervention is not always useless when we operate a little too late. There are cancers of slow course where the continuous invasion and infection by continuity of tissue preponderate over the invasion of lymphatics and the carriage of cells to a distance. It would be going too far always to refuse the advantages obtainable from the improvements made in the technique of abdominal hysterectomy. The cases are rare and difficult to form a judgment of, but it is legitimate to operate by the high method in the case of a very moderate invasion, apparently limited to the vaginal wall, sufficient to put the other method out of court, but excluding the idea of a real diffusion of the cancer, and in presence of a slowly developing tumour, when the surgeon has been able to follow the evolution of the disease long enough to judge that its pursuit will not be altogether illusory. For this reason Richelot has welcomed abdominal hysterectomy, without believing it a sovereign remedy and without adopting it exclusively, because it enables the operator to go a little further afield to seek for favourable cases. He must, however, walk in this path with the greatest caution if he does not wish to meet with numerous disappointments. In conclusion, Richelot said his object was to show how vaginal hysterectomy effects cures which appear to be definitive, when it is done early enough to prevent invasion; that it gives prolonged survivals, and that abdominal hysterectomy in an additional resource in a small number of cases, but performed deliberately in cases of invading cancer is an imprudence, and in cases of limited cancer an illusion. This means that he differs widely from those who see in the former an operation always incomplete and necessarily only palliative, and in the latter the only procedure by which everything can be removed, and therefore the only one which is logical and rational. He is tempted to invert the proposition and to say that the truly curative operation is that which precedes cancerous infiltration, while the palliative operation is that which professes to pursue it. He admits that this formula may be too absolute, as it is difficult to find words to express all clinical shades of difference and possibilities.

PROFESSOR DMITRI DE OTT (St. Petersburg) dealt with the surgical treatment of cancer of the uterus. The following are his conclusions: (1) Surgical treatment is now the sole means of successfully combating cancer of the uterus. In a whole series of cases it is possible to effect a complete cure by operation. The results of the radical cure are undoubtedly made better by early diagnosis based on a histological examination of all doubtful cases. (2) The biological purpose of the womb as well as the peculiarities of its anatomical structure necessitate a special study of cancer of the uterus, and observations on cancer in other parts of the body as well as the conclusions drawn from those cases can be applied to the uterus only after verification for the particular case. (3) Total extirpation of the uterus must be performed in all cases of cancerous lesion of any part whatever of the organ, as this procedure gives the best guarantee against recurrence. (4) Removal of the ovaries and appendages generally should be practised only when there are special indications. (5) A radical cure is obtained by following the principles set forth above. The enucleation of retroperitoneal glands, recommended especially of late, should be practised only by the abdominal route. It should not be accepted as the rule, being warranted neither by theoretical considerations nor by fairly convincing clinical facts. It should also be looked upon as much more dangerous, and the indications for it are not sufficiently established. (6) Total extirpation of the uterus by the vaginal route is preferable to all other methods. The improvement of the technique now makes it possible by this route to overcome all the obstacles which quite recently made it necessary to have recourse to cœliotomy, exposing patients to all the risks of that procedure. (7) Morcellation in cases of considerable size of the organ or complication with fibrous tumours, which are frequent in cases of cancer of the uterus, is to be regarded as a conquest of great value in gynæcological surgery. (8) In cases of pregnancy complicated with cancer of the uterus extirpation is indicated, as well as where there is no pregnancy. The vaginal route is to be preferred. This method of operating may be practised up to the seventh month of pregnancy inclusive and presents but little difficulty in view of the possibility of lessening the size of the organ by removal of the ovum after opening up of the *cul-de-sac* and suture of the uterine vessels. If pregnancy is more advanced, in view of the viability of the child cœliotomy is the operation of choice, although one may have recourse to extirpation by the vaginal route after having delivered the child by vaginal Cæsarean section. (9) It is better not to close the wound leading into the abdominal cavity after total extirpation of the uterus and to confine oneself to light plugging with iodoform gauze. (10) The ovaries having been saved, sexual life undergoes no modification after extirpation of the uterus. (11) The remote results of the surgical treatment of the upper part of the uterus (cancer of the body) are infinitely more favourable than those of the lower part (cancer of the cervix). (12) Total extirpation of the uterus should be practised even in very advanced cases, for by means of that operation one can most effectually relieve the patients and postpone the fatal termination. In certain cases owing to the want of clinical precision in defining the limits of the new growth one may even succeed in obtaining a radical cure. (13) The mortality of the vaginal extirpation of the uterus can easily be reduced to a minimum; in any case it does not exceed 2 per cent. (14) In the series of cases operated on by the author a radical cure (over six years) was obtained in 10 per cent. Extirpation was practised in all cases of cancer, even those in which the disease was relatively advanced.

DR. THOMAS S. CULLEN (Baltimore) presented a communication on the treatment of Carcinoma of the Uterus. He briefly referred to the gradual improvement in the operation for carcinoma of the uterus, commencing with amputation of the cervix, as practised by Schroeder and his contemporaries; abdominal hysterectomy, as recommended by Freund; the catheterisation of the ureters, as employed by Pawlik and Kelly; and the more radical operation, consisting in the removal of the iliac glands, as advocated by Ries, Rumpf, and Clark. Cullen then pointed out the danger of implanting carcinomatous into healthy tissue, as is very likely to occur when the radical operation is performed. He next described in detail the operation as performed by Werder of Pittsburg. In this operation the chances of implanting carcinomatous tissue are reduced to a minimum. The various stages in the abdominal operation, where the cancer is limited to the cervix, are as follows: (1) Removal of broken-down carcinomatous cervical tissue, preferably a few days before; (2) insertion of ureteral bougies if desired; (3) ligation of the ovarian vessels and round ligaments; (4) freeing of the bladder from the uterus and broad ligaments; (5) opening of broad ligaments, location and freeing of the ureters to the points at which they enter the bladder; (6) ligation of the uterine vessels near their points of origin; (7) dissection of bladder free from vaginal vault; (8) dissection of rectum from vaginal vault; (9) removal of pelvic lymph glands; (10) freeing of vaginal fornices; (11) closure of pelvic cavity by uniting the vesical peritoneum with that of the rectum, an assistant meanwhile making strong traction on the cervix from below; (12) closure of the abdomen; (13) ringing of the vaginal vault with a thermo-cautery or knife, thus freeing the uterus and its

surrounding vaginal mucosa; (14) application of a light gauze pack to the space left in the vaginal vault. As will be noticed the uterus is freed on all sides, the vagina dissected loose from the bladder and rectum, and the pelvic and abdominal cavities closed before the operator comes in contact with the carcinomatous cervix. Even then there is little or no danger of transplantation of carcinomatous tissue. Cullen advised this operation in all cases where the patient is not excessively stout. Of course in such instances one has frequently to rely on a vaginal operation entirely. In adeno-carcinoma of the body of the uterus the same operation may be performed, but the wide removal of the vaginal mucosa is not necessary. The speaker then briefly analysed one hundred and seventy-six of carcinoma of the uterus occurring in the Johns Hopkins Hospital during the last six years as follows: *Variety of Carcinoma.*—Operative cases: Squamous cell carcinoma of the cervix 61, patients well January 1st, 1900, 13 (21 per cent.); adeno-carcinoma of the cervix 12, patients well January 1st, 1900, 12 (16 per cent.); adeno-carcinoma of the body of the uterus 30, patients well January 1st, 1900, 19 (63 per cent.). *Cases coming too late for operation.*—Squamous cell carcinoma of the cervix, 62 cases; adeno-carcinoma of the cervix, 6 cases; adeno-carcinoma of the body, 5 cases; total, 76 cases. The prognosis is most favourable in adeno-carcinoma of the body; least promising in adeno-carcinoma of the cervix.

---

(112) Cervical Metritis.

PROFESSOR S. POZZI (Paris) introduced a discussion on this subject. He formulated the following conclusions:—(1) Acute or chronic inflammation of the cervix may exist for a long time isolated without invading the body of the uterus. (2) Nevertheless, acute lesions of the cervical mucosa easily spread to the mucous membrane of the body, and chronic lesions of the cervical parenchyma of inflammatory origin (sclerous and sclero cystic degeneration, partial or complete), quickly react on the nutrition and the anatomical state of the body of the uterus as a whole. (3) The operation of trachelorrhaphy is inferior to bi-conical resection of the cervix, more or less modified according to circumstances. It should be given up. (4) There is a large number of acute, subacute, and chronic inflammations of the cervical mucosa in nulliparous women, which are associated with narrowness of the external orifice and the insufficient drainage resulting therefrom. The most important part of the treatment is then the operative reconstitution, in a permanent manner, of a sufficient orifice for the uterine cervix.

DR. DOEDERLEIN (Tübingen), said that to-day the causes of inflammatory diseases of the canals or cavities of the body communicating with the exterior should first of all be sought for in a microbic infection. Modern bacteriological researches had led to the conclusion that it is the external orifice of the uterus which forms the boundary between a lower portion of the genital organs containing micro-organisms, and an upper part not containing micro-organisms. Therefore there are, as a rule, no microbes in the cervix or its mucus. Micro-organisms introduced naturally, or artificially during experimental researches, are destroyed by the alkaline mucus of the cervix. Owing to this bactericidal property the cervix of the uterus not only protects itself against microbes but at the same time defends the uterus, tubes, and peritoneal cavity against the micro-organisms which penetrate into the vagina and live there. Among the pathogenic parasites or germs which penetrate into healthy and living tissues and set up inflammation there are only two species, the gonococcus of Neisser and the bacillus tuberculosis of Koch, that are of any etiological significance in regard to cervical metritis. Whilst the localisation of gonorrhœa in the cervix is very common, tuberculous infection limited to that region is extremely rare. The means of protection of the cervix are powerless against gonococci; the other germs that penetrate with the gonococci, or after them, cannot establish themselves there, so that mixed infections in that part are improbable. Tuberculous, syphilitic, and diptheritic diseases of the cervix of the uterus are distinct maladies, very different from what is called cervical metritis. If one considers non-infectious cervical metritis, it is recognised that lacerations of the cervix play a large etiological part, as well as all the causes and diseases which produce metro-endometritis. The mucous membrane of the cervix is disposed to hyperplasia, polypi and indurative or erosive lesions; that of the vaginal portion, on the other hand, is prone to changes of the epithelium, that is to papillary and follicular erosions. The pavement epithelium is replaced by a cylindrical epithelium which has a tendency to extraordinary proliferation. Anatomo-pathological lesions are well known and beyond all question, but, on the other hand, the etiology requires further study both by bacteriological research and clinical observation.

DR. MENDES DE LEON, of Amsterdam, said that the pathological lesions of the cervix which are held to characterise the syndrome, cervical metritis, are from the clinical point of view difficult to separate from chronic inflammations of the body of the uterus, notably from those of its mucous membrane. That which it has been agreed to designate by the name of "erosion" plays an important part in the symptomatology of these changes. The divergent opinions concerning its origin may be grouped in four principal classes: (1) Erosion is looked upon as a loss of substance desquamation of the pavement epithelium on an inflamed site, which really constitutes a first degree of ulceration (C. Mayer). (2) Erosion is regarded as a metaplasia of the pavement or cylindrical epithelium co-existing with a glandular new formation (Ruge and Veit). (3) Erosion is considered partly as a congenital histological ectropion and partly as a true ulceration of the cervix (Fischel). (4) Erosion is equivalent to ectropion (Doléris). According to the opinion of Doléris ectropion is, properly speaking, a spot denuded of epithelium. Thus the presence of cylindrical epithelium would be no proof of metaplasia, but rather evidence of an ectropion of the cervical mucosa. If beneath this glands are found, they should be regarded as the cervical glands of the ectropic mucous membrane, and not as new growths, as is maintained by Ruge and Veit. From the clinical points of view this question is of merely secondarily interest to gynæcologists unless co-existing phenomena give rise to the suspicion of malignant new formation. In opposition to certain authors who speak of metritis only when the disease has developed under the influence of micro-organisms, Mendes de Leon holds that two forms of inflammatory process in the uterus can be distinguished—namely, a bacterial and a non-bacterial form. The importance of this distinction is unquestionable from the theoretical point of view. It would also be of great practicable value in concrete cases. But in view of the fact that it is almost impossible to discover the etiology of chronic forms, it is more rational to judge according to the clinical syndrome (history, pathological anatomy) if one has to do with a catarrhal endometritis properly so called, or a pseudo-endometritis (hypertrophy, hyperplasia). According to pathological anatomy, the catarrhal form is characterised by the presence of leucocytes in the stroma. Pseudo-endometritis is distinguished by an exuberant glandular proliferation, and by increase of the stroma, whilst in atrophy of the mucous membrane the latter is composed almost entirely of atrophied connective tissue. The symptomatology of the metritis of French writers perfectly agrees with that of the endometritis recognised by the author, as does the pathological anatomy as far as the mucous membrane is concerned. But, on the other hand, inasmuch as it happens often that many cases of endometritis are not characterised either by increase in the size of the uterus or by induration of the cervix while the muscular tissue of the organ has suffered no change, it follows that the term "metritis" is not always applicable. It is only in the gonorrhœal and septic affections of the uterus that the inflammatory process regularly penetrates more deeply down to the muscular substance. In the etiology of non-infectious affections of the endometrium one recognises the preliminary influence of long-standing, passive or active, hyperæmia of the genital apparatus such as might be caused by physical fatigue, colds, the habit of taking cold baths at the menstrual period, chronic constipation, *coitus reservatus*, masturbation, as well as *post-partum* or *post-abortum* subinvolution; lastly, fibromyomata and displacements of the uterus. As

for infectious septic or specific inflammations of the uterus, their origin must be sought in bacteria of all kinds whose presence in the lower part of the genital canal, even in perfectly healthy women, has been proved beyond doubt. There is particularly a puerperal endometritis, where not only the enlargement of the entrance to the uterine cavity facilitates invasion by microbes, but where the internal surface of the organ, riddled with wounds, with its blood and lymph vessels open, offers a favourable field to the micro-organisms which have penetrated into it. But in the non-puerperal uterus also an inflammatory disease may develop in cases where any lesion of the endometrium (as after operation or artificial abortion) coexists with invasion by pyogenic germs (staphylococci and streptococci), while certain specific bacteria, such as gonococci and the bacilli of tubercle, syphilis, or diphtheria, are capable by themselves of setting up inflammation in an intact mucous membrane. Most of those agents, whether combined or not with disorders of circulation, can induce the syndrome of cervical metritis. Here one is met by the question whether the symptoms that have been mentioned are rigorously limited to the cervix. It is improbable that an inflammatory process which has taken possession of an organ entirely covered with mucous membrane, and continually in contact with all sorts of harmful influences, would be arrested by a boundary so easy to cross as the ostium internum. Moreover, it has been shown by the clinical phenomena as well as by the pathological anatomy that partial affections of the uterine mucosa must be classed among exceptional cases. There is a difference of opinion with regard to the correlation of cervical catarrh with catarrh of the body. Pozzi, in his *Manual of Gynæcology*, says on this subject: "The localisation of the disease is usually at the cervix. This is the cervical catarrh of certain authors. I believe that it is wrongly described as a circumscribed lesion; in such cases there is always a concomitant change of the mucosa of the body. The practitioner must act accordingly on pain of disappointment." Mendes de Leon is completely of the same opinion. Some years ago as the result of researches undertaken by him in conjunction with Dr. Van Tussenbroek he was able to satisfy himself that among 100 specimens of mucous membrane examined in only 3 cases was there isolated cervical catarrh. On the other hand, he found catarrh of the body in 55 cases. In 39 of these it was circumscribed, while in 16 it was combined with cervical catarrh. When the presence of symptoms indicative of cervical metritis has been ascertained it is difficult to prove or to exclude affection of the mucous membrane. Erosions of of all forms, an open cervix, or cyanotic engorgement of the cervix certainly indicate the existence of cervical metritis, whilst the source of metrorrhagias and menorrhagias is usually found in the mucosa of the body, provided they do not arise from cervical polypi or very extensive papillary erosions which bleed at the slightest touch. In the absence of erosions, and when nevertheless there is a more or less abundant mucous or purulent secretion, it is all but certain that one has to do with a catarrh of the body. Moreover, the preponderance of indirect and reflex symptoms such as fatigue, mental depression, headache, anorexia, dyspepsia, palpitations, tenesmus of the bladder, incontinence of urine, etc., especially shows the existence of lesions of the mucosa of the body, one of the principal symptoms of which consists in pain and abundant metrorrhagia following introduction of the sound. The treatment of cervical metritis almost always in connection with affections of the body has, particularly in France, formed the subject of many discussions and set in motion a large number of pens. It appears from the literature of the subject that, whilst as far as the pathogeny and symptomatology are concerned the two lesions are generally to be considered separately, the same thing does not hold good in regard to treatment. There has but seldom been any question of indications for exclusive treatment of the cervix, although the technique of such treatment has been keenly debated. Even in pronounced cases of cervical catarrh with marked ectropion, where surgical treatment has been regarded as indispensable, most authors recommend a preliminary curettage. In general the indications for this treatment really exist, as the mucosa of the body is almost always found to be affected at the same time; while in doubtful cases where the clinical symptoms are not distinctly marked, one can always invoke the aid of the microscope to confirm the diagnosis. Nevertheless, it appears to Mendes de Leon irrational if, in spite of long continued local treatment, one has failed to conquer a refractory purulent leucorrhœa, whether accompanied or not by erosions and ectropion, to decide on amputation of the cervix before having thoroughly convinced oneself of the state of the mucosa of the body; because when the latter is equally affected, as is generally the case, curettage is indicated as being capable of giving much better results than so mutilating an operation. As to the numerous methods of treatment and operative procedures in use for the cure of cervical metritis the author declines to express any opinion, as he has seldom found occasion to apply treatment to that condition exclusively. He sums up his views in the following propositions: (1) One must not consider or treat cervical metritis as an isolated affection, seeing that in the large majority of cases it is associated with a similar affection of the body of the uterus. (2) The term "cervical metritis" should in most cases be replaced by that of "cervical endometritis" since the inflammation of the mucous membrane, but seldom coexists with a lesion of the deeper tissues.

DR. JONNESCO (Bucharest) described himself as exclusively a partisan of the high method in the radical treatment of uterine cancer. He had done vaginal hysterectomy in 8 cases with 8 operative successes, but in all the cases recurrence took place within eight months at the outside. Now in the case of spreading growths, after noting the extent of the lesions, he ties all the arteries supplying the uterus, closes the abdomen, and removes or scrapes away the carcinomatous masses. In limited non-invading cancers he does abdominal hysterectomy, removing the upper part of the vagina and completely emptying the upper and lower pelvis. He had done this operation 12 times with 6 deaths, but in spite of this large mortality he held that the operation was legitimate.

DR. MORISANI (Naples), without expressing absolute preference for either abdominal or vaginal hysterectomy, held that the former was suitable for extensive neoplasms, the latter for limited tumours. But he insisted that hysterectomy should not be used in a pregnant woman. If the pregnancy was in the early stage he contented himself with partial operations or electrolysis. Near term his first object was to deliver a living child; then he performed hysterectomy, abdominal or vaginal, acording to the seat and extent of the neoplasm.

DR. FRITSCH (Bonn) stated that in Germany there is a tendency to use the high route in the treatment of cancer. His own practice is to do the high operation when the parametrium is attacked; in simple cases without peri-uterine invasion he does vaginal hysterectomy.

DR. DÉLAGÉNIÈRE (Mans) declared himself a partisan of the high route, and insisted on preliminary ligature of the hypogastric and uterine arteries.

DR. BOUILLY (Paris) gave the following as the results of his treatment of cancer by vaginal hysterectomy. In a first period (1886 96) he operated in 127 cases; in a second (1897-1900) he had operated in 56, being a total of 183 operations. Better antisepsis and improved technique had diminished the mortality in the second series to 5.35 per cent., as against 19 per cent. in the earlier series. Deducting from the 183 cases 28 in which death followed the operation and 21 in which the patients were lost sight of, there remain 144 operated on in the last 14 years and followed up. Of that number only 18 are still living, and in 2 of them (1 operated on 3 years and 4 months, the others 2 years and 8 months ago) recurrence has taken place. Of the 16 others who remain in apparent good health 1 was operated on 12 years ago (in this case the histological examination appears to give some reason for doubt as to the nature of the tumour), 1 four years and three months, 4 three years, 4 more than a year and a half, 3 one year and less ago, while 5 have been operated on since the beginning of the present year. Taking all his cases together the average survival has been two years.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF MILITARY MEDICINE AND SURGERY.

(113) Etiology and Prophylaxis of Typhoid Fever in Armies in the Field.

Dr. Vincent, Médecin-Major de 2e classe, Professor-Agrégé at the Val-de-Grâce Military Hospital, said that typhoid fever is a constant accompaniment of all wars, and in many of them has been more murderous than the fire of the enemy. The pathogenic factors are the same as in time of peace, but in the field their noxious influence is at its maximum. *Predisposing Causes.*—Among these must be counted the age of the soldier, his customary country origin, the time of mobilisation and military operations (summer, autumn), monotonous and imperfect diet with resulting digestive disturbances, inevitable deficiencies in bodily hygiene and in clothing, hot climate as in colonial expeditions, aggregation of troops and overcrowding in cantonments, bivouacs, forts, and towns, besieging or besieged forces, long continuance of war, the depression of defeat. Over-fatigue is the most formidable predisposing factor. *Determining Causes.*—The typhoid bacillus is ubiquitous. It may remain in the latent state and in the digestive canal and multiply there under the influence of the predisposing causes; from this ensue epidemics that are apparently spontaneous (Kelsch). Other causes are the importation of the germ by troops arriving from infected garrisons, and contagion from man to man. There is danger from clothes, blankets, drinking and soup cans, platters, etc., that have been used by men suffering from typhoid latent or declared. Transmission by ingesta, drinking water, plays a most important part (Egyption expedition, Turko-Russian, Spanish-American, South African wars, etc.). Food brought from infected regions and vegetables may carry the disease. Flies play a part, especially in colonial countries, in the contamination of food and clothing, and of the face and hands. The soil is the habitual receptacle of the typhoid bacillus, which may live very long in it. Impregnated with urine and specific dejecta from commencing cases and others of the ambulatory type, befouled by the excrements of men and animals, by offal, etc., the soil may transmit the germ to the soldier either directly or by the medium of drinking water, foot-gear, and clothing. The air carries about pathogenic dust resulting from the desiccation of the infected soil. 2. The necessities of war make the prophylaxis of typhoid fever very difficult. *General Prophylaxis.*—At the commencement of mobilisation all men out of health should be eliminated or drafted to the auxiliary services. At the beginning of the campaign there should be given to each man, or at least to each officer, a leaflet of instructions setting forth the principal rules of the prophylaxis of infectious diseases, particularly of typhoid. During the period of concentration and during active operations care should be taken to prevent over-fatigue as far as is compatible with the exigencies of war. For colonial wars only men should be chosen of at least 25 years of age, and the expeditionary force should be followed by a large number of bearers, etc. The purity and variety of food, individual cleanliness, the hygiene of cantonments, bivouac, and camps, and that of latrines (which should be lighted at night), protection against the plague of flies, the ventilation of tents, huts, etc., the sanitation of fields of battle—all these things should be the object of constant and rigorous supervision. Suspicious wells should be placed out of bounds and guarded. Only filtered or boiled water, or better still light tea or coffee should be used. Alcoholism should be prevented. *Special Prophylaxis.*—The value of antityphoid vaccination by Wright's method has not yet been established. Each Army Corps should be provided, as is the case in the German and American armies, with a bacteriological outfit for use in the field, so that the early cases of an epidemic, which often pass unnoticed, may be recognised. Troops coming from infected garrisons should if possible be made to camp or bivouac apart. Sick men should be enjoined to report themselves without delay. The most serious cases should be sent to special hospitals. The evacuation of other cases of typhoid and suspected cases far from the zone of operations is possible, and should be carried out in the early days of the disease. It seems to be necessary to establish special hospitals for typhoid cases. The dejecta and everything that may have been touched or soiled by the sick should be disinfected or sterilised. In cantonments, localities and dwellings infected with typhoid fever should be avoided. Quarters should be cleansed and ventilated, and if need be disinfected. Soil, water, and air should be protected against contamination by specific faecal matter. Dejecta and filth should be burnt, or, if that is not possible, disinfected and buried. Cantonments should not be kept long in the same place. In temporary camps, besieged places, and besieging armies, the same rules for combating contamination of the soil, water, air, food, etc., should be observed. If typhoid fever spreads the camp should be abandoned. A detail should be left there to carry out disinfection, and a new camp should only be established after a bivouac for at least fifteen days so as to give time for incubating cases of typhoid to declare themselves.

(114) Prophylaxis of Dysentery in Armies in the Field.

Dr. Antony, Médecin-Major Principal de 1e Classe, Professor at the Val-de-Grâce Military Hospital, after referring to the fact that the nature of the germ of dysentery is unknown, and pointing out that the secondary causes—cosmic conditions, atmospheric changes, over-fatigue, nature of food, infection and contagion in time of war—act simultaneously and acquire their maximum of intensity, said the most vigilant prophylaxis could do little against the first four of these; it could only attenuate their immediate effects. War will always expose armies to sufferings and privations of all kinds and to bad weather, often without any shelter, and the most careful commander will never be able to spare his troops hard work and the overfatigue resulting therefrom. This can be borne by strong, hardened men if they are properly cared for; but recruits and weakly men have always shown themselves incapable of resistance. It is necessary, therefore, that these should be kept away from the fighting line until their military training is complete. To act otherwise with the object of putting into the field a larger effective force can only lead to disaster. As regards food, the rations should never be solely composed of preserved food when it can be helped. Intemperance and all forms of excess should be severely repressed. For the purification of water every available method should be used, but the most practical and certain is boiling. Soldiers willingly adopt these precautions if tea or coffee is served out to them for use with the water. As the sanitary service is not adequate to cope with the necessary work of disinfecting hospitals and the sanitation of battlefields, there should be organised in time of peace a special service for those purposes which should be in a condition to set to work from the very beginning of mobilisation. A service of this kind was tried with success by the Russians in 1877. In hot countries, where malaria and dysentery acquire a special character of frequency and intensity, besides the precautions just referred to, care should be taken, if possible, not to carry out military operations during the time of year when these diseases generally prevail, and the troops should be subjected to prophylactic treatment by quinine.

(115) Etiology of Dysentery in Armies in the Field.

Dr. Simonin, Médecin-Major de 2e classe, Professor-Agrégé at the Val-de-Grâce Military Hospital, said the history of ancient and mediæval wars as well as that of modern campaigns, even the most recent, showed that dysentery is one of the most constant factors in the morbidity of troops in whatever region the warfare is carried on. Its outbreak appears almost inevitable and always occurs very early. It may show itself at once frequent and grave as well in temperate as in tropical climes. The pathogenic agent has not yet been definitely

determined, and the uncertainty on this point tends to invalidate the opinion of clinicians who are prone to regard this affection as a well-defined entity of unequivocal nature whatever be the circumstances and the regions in which it happens to prevail. At present it appears as if the term "dysentery" represents merely a pathological syndrome. Some ascribe its causation to animal parasites (amœbæ). Others have found the etiological factor in a number of microbes which grow in the organism of which they are more or less habitual inhabitants. Some, again, have associated both microbes and amœbæ in the etiology of dysentery. However this may be, the most general tendency is to consider the morbid agent as an ordinary inhabitant of the human economy which in certain circumstances acquires a special power of growth and virulence. Dysentery appears most frequently to originate in infection. The virulence of the morbid agent once developed appears to be maintained in external media for a certain time. It may consequently be said that the disease originates in ordinary causes which may deteriorate the organic medium and allow the abnormal development and acquisitton of virulence by germs that are ordinarily harmless. The affection thus started seems to propagate itself subsequently by means of the contagion generated by these germs which have become virulent. In armies in the field the influences making for the production of dysentery are manifold. First of all come cosmic conditions (climate, heat, season). Heat particularly helps to make dysentery the principal disease that attacks troops in tropical countries. The influence of atmospheric changes and particularly of sudden chilling of the body or the abdomen plays a considerable part in the onset of diarrhœic and dysenteric fluxes. In addition to these etiological factors must be counted bad and insufficient food, the prolonged use of tinned foods, salt pork, green fruit, weavly biscuit, etc. Intemperance in drink and in food, especially in tropical countries, is also a cause. At all times and in every country the use of water, non-specifically fouled by organic or excrementitious matter, seems to be capable of inducing dysentery. Over-fatigue, which is unavoidable in war, by accumulating products of combustion in the organism engenders a true auto-intoxication, diminishes the phagocytic resistance, and favours in the highest degree the acquisition of virulent properties by the germs which cause dysentery. Soon, also, there intervenes a new infective factor, the importance of which most frequently becomes predominant, especially if the war is protracted within restricted territorial limits. This is the pollution of the soil and to a lesser degree of the air. The accumulation of organic refuse and of the dead bodies of men and animals gives this factor a very formidable potency, particularly in camps and beleaguered towns. When dysentery has made its appearance most often under the form of diarrhœa it spreads rapidly in armies, owing to the specific infection of the place and the inevitable aggregation of persons multiplying contacts. Then comes in anew the influence of the water, the soil and the dust of dwellings specifically polluted by virulent dejecta. These again transmit the infection by direct contact or by fomites. Arising most often in the points of concentration of troops dysentery is rapidly disseminated along the great lines of communication, at the halting places and cantonments where troops succeed each other. Most frequently armies infect the populations through which they advance; sometimes, also, they receive from them the infection which they themselves sowed in the first instance. From all these causes, widespread and interminable, pandemics often arise. Dysentery then prevails permanently. In temperate climes it is often associated with typhoid fever, in tropical climates with malaria. If the war continues the infection rages, together with typhus and scurvy, among the exhausted and famished troops.

(116) Extemporaneous Methods of Water Purification.

SURGEON-MAJOR SCHUCKING, of the Austrian army, said that of the various methods of purification there are only two that can be taken into account for the use of troops in the field, namely, (1) filtration, (2) purification by the addition of chemical agents. Among filters aiming at the sterilisation as well as the clarification of water, the Berkefeld-Nordtmeyer alone is so constructed as to meet the exigencies of war. But, although well adapted for use in field stations, it can only be carried in baggage waggons. Portable filters only clarify muddy water. The use of them, therefore, requires to be supplemented by some means of destroying microorganisms. After extensive experiments and researches (Traube, Lode, Kratschmer, Vogel) such a means has been found in hypochloride of calcium. In a dose of 8 milligrams of chlorine to a litre this chemical agency certainly kills all bacilli in thirty minutes.

DR. VINCENT, head of the Bacteriological Laboratory of the Military Hospital of Antwerp, said boiling gives absolute security, and requires no special apparatus, and the tastelessness of the water can be qualified with tisane or weak coffee. The filters in most general use are the Berkefeld and Pasteur. The experience of numerous observers as well as Dr. Vincent's own make him regard these as about equally valuable. But even when they are carefully sterilised, these filters do not give a water rigorously and constantly aseptic. Among the few germs which they allow to pass there are saprophytic as well as pathogenic organisms. After a few days they must be sterilised anew. Two methods particularly are used for this purpose. One of these is heat, which is the best, but also the longest. The other (Guinochet) is based on the use of potassium permanganate. This is more rapid and more practical, but does not produce absolute sterilisation. Dr. Vincent, however, considers it sufficient in view of the fact that there are always a few germs which pass even when sterilisation has been perfect.

(117) Plague Epidemics in the Far East.

MM. SIMOND AND YERSIN said plague does not rise spontaneously in a place. It does not even reappear there when it has disappeared for twenty years unless it is reimported. This fact has been established in regard to Constantinople, Venice, Genoa, and Messina epidemics in 1347 when the scourge came from Jaffa; in regard to that of Marseilles in 1720, when it came from Syria, and in regard to that of Cutch-Mandvi in 1812, when it was imported from Mecca. A study of recent epidemics leads to the same conclusions. The following principles may be laid down: (1) That plague spreads around a centre, like a spot of oil, by circular extension; (2) that the transportation of a primary focus to a distant centre may rapidly be brought about if there are direct and rapid communications between these points; (3) that the contamination of distant centres is exceptional if they are not connected with the focus by railways, or lines of navigation. In the Far East plague has gone forth from its endemic foci by the same road as merchandise. Its march, at first very slow, has become accelerated in proportion as it reached points where human movements were most rapid. On the other hand, neighbouring regions separated from the foci by natural barriers have been protected. The Gharwhaal in the Himalayas has not infected India, nor has the Yunnan in China infected Tonkin. It is from the Yunnan that have come the germs which have spread over the whole world. They took 30 years (from 1850 to 1880), following the rivers and roads of communication to reach Long-Tcheou and Pakoi. In 1893 English diplomacy succeeded in getting the Canton River opened to trade. The plague starting from Long-Tcheou reached Canton and Hong Kong, whence in four years it spread to the five parts of the world. It is useless to recall the origin of the plague of Bombay, but it is more important to determine at what point the scourge issued from India. The port of Cutch-Mandvi seems to be the starting point. The sanitary police is admirably organised at Bombay and at Karachi; but arrival at and departure from Cutch-Mandvi, where there are no Europeans, requires no formality. This native port is the centre of a very busy trade, and is in constant relation by means of small sailing ships with Madagascar, Zanzibar, the Mauritius, Jeddah, and the Persian Gulf. Whilst the infection derived from Long-Tcheou was spreading so far, Pakhoi was contaminating the surrounding little boat ports in the island of Hainau, at the mouth of the Vinh in Tonkin, in the bay of Quang-Tcheou-Van, and at Nha-trang. The first time in the memory of man that plague raged in Cochin China was when it reached the villages at the River Vinh. Without any measures of precaution, it remained localised in two or

three villages, where it died out without making any victims. It was observed at Quang-Tcheou-Van by the French warships stationed in that bay in 1899. Certain villages where the plague ranged among human beings, and especially among rats, were evacuated. The population fled and went to camp out in the fields. According to Fathers Maréchal and Ferrand, the disease showed itself in 1891 at Chek-chen, a town situated on the west of the bay, which since that time has remained an endemic focus. For a moment it was feared that the epidemic of Nha-Trang had come from the Pasteur Institute, where plague cultures were kept. A minute inquiry, however, proved that this epidemic also had come from Pakhoi. Three months before in the village of Culas, situated opposite Nha-Trang, on the opposite bank of the estuary, an unusual mortality had been observed, which was found to be caused by plague. The first person attacked had dwelt on the isle of Bai-Meou, a port which is in constant relations with Pakhoi. The history of this epidemic showed the inefficacy of disinfection by antiseptics, and the efficacy of the destruction by fire of the contaminated huts. It also afforded an opportunity of showing the advantages of serumtherapy, both as a curative and a preventive method. MM. Yersin and Carré tried vaccination with attenuated viruses at Nha-Trang. They noted that by aging of the cultures it was possible to obtain races of plague bacilli possessing all degrees of virulence, from bacilli which killed a rat in forty-eight hours to microbes that did not kill them at all. They were passed through cultures which caused the death of 80, 50, 20, and 10 per cent. of the animals inoculated in a space of time varying from four to fifteen days. After long trials MM. Yersin and Carré obtained a plague bacillus which killed only 20 per cent. of rats inoculated, and which they called the C bacillus. The germs deprived of virulence do not vaccinate. The animals which have resisted plague bacilli of feeble virulence are vaccinated. Immunity seems to be acquired at the end of fifteen days. As to whether it persists, an experience of three months is insufficient to determine. The virus which kills 40 to 50 per cent. of the rats was inoculated in monkeys, which showed only a passing *malaise*, and which finally resisted the virulent bacillus. Dr. Yersin inoculated the C bacillus on himself without any other result than slight feverishness and pains in the limbs. The inoculations are made with a lancet, as in Jennerian vaccination. This is the chief advantage of the method which has a better chance of being accepted than vaccination with a syringe.

(118) Prophylaxis of Tetanus in Hot Countries.

Dr. Calmette, Director of the Pasteur Institute of Lille, said tetanus is very frequent in the most of the French Colonies in the torrid zone, and in particular on the West Coast of Africa in Guiana and in the Antilles. It specially attacks young children, and in Cochin China many newborn babes succumb to the infection. The black race appears to be most sensitive, the white coming next in the order of susceptibility, and the yellow third. During the colonial wars of the second half of the nineteenth century the mortality due to tetanus among the wounded averaged 3 to 5 per cent. This figure is not high, but the knowledged acquired as to the prophylaxis of the affection since the discovery of its specific microbe by Nicolaïer makes it a duty to preserve troops from it and to protect the lives of thousands of native children whom it decimates every year. The etiology of tetanus in hot countries is almost always to be found in the contamination of wounds by bits of earth or animal dejecta. The tetanus of newborn babes is due to infection of the umbilical wound by dirty linen or dressings. The measures that should be taken to prevent this cause of mortality are: (1) To make general in the colonies, in the hospitals, ambulances, and columns on the march the use of antitetanus serum to prevent tetanus in wounded men where the wounds may be soiled by earth or contain pieces of clothing. All cases of gunshot wounds should after the first dressing at the ambulance receive a preventive injection of 10 cubic centimetres of antitetanus serum. (2) In all tropical colonies native midwives should be educated and authorised to attend confinements only after giving proof of sufficient knowledge to ensure at least elementary antiseptic treatment for the women and newborn children. For this purpose there should be organised in each centre of colonisation where there are medical men elementary courses of instruction with practical exercises in the native hospitals. In these instructions special stress should be laid on the need of rigorous cleanliness in the dressings of the umbilical cord. By this simple and inexpensive measure there would be saved every year a very large number of lives precious for the economic future of the countries in question.

(119) Pathogeny and Prophylaxis of the Bilious Hæmoglobinuric Fever of Hot Countries.

Dr. Firket of Liége does not recognise a parasitic infection from the outside immediately preceding the attack to be a sufficient cause of bilious hæmoglobinuric fever. It is prepared by a chronic change in the organism, and directly brought on by the action of multiple factors that would not be adequate to produce it in a perfectly healthy subject. The preparatory changes involve the various viscera, and especially the hæmatopoietic organs resulting in abnormal fragility of the blood corpuscles. They have, as principal cause a preceding malarial infection, whether that infection has manifested itself by repeated febrile attacks or has established itself slowly with a minimum of pyrexial reaction. To the influence of malaria must be added that of unfavourable hygienic conditions, hot climate, absence of comfort, depression, and drink. The effects of these various etiological factors tend to become cumulative in proportion as the sojourn of the individual in the unfavourable medium is prolonged, and thus make him liable to the action of secondary causes. These may be common non-specific influences, notably cold, fatigue of all kinds, violent emotions, in fact, everything that can disturb the unstable equilibrium of the tissues. It may be a fresh attack of malarial fever suddenly increasing the alteration of the blood, or it may be an intoxication; perhaps in certain cases an auto-intoxication of gastro-intestinal origin; at other times a drug intoxication by quinine. That medicinal substance has been justly accused in certain cases, but it should not be considered as an exclusive cause, and even in the cases where its pathogenic *rôle* appears to be established it acts only by favour of a predisposition. In these conditions the prophylaxis of the bilious hæmoglobinuric fever of hot countries in great measure corresponds with that of malaria. The principles are, on the one hand, to avoid infection particularly by the systematic preventive use of quinine; on the other, to combat the effects of infection when contracted by a rational treatment and by all the necessary elements of comfort to facilitate the restoration of the diseased organism; to reduce the usual period of residence in dangerous climates; lastly, to avoid as far as possible all secondary causes, and as regards the use of quinine to make the indications and the dosage more exact.

(120) Etiology and Prophylaxis of Endemic Bilious Hæmoglobinuric Fever.

Dr. Clarac said bilious hæmoglobinuric fever had never been observed in a person absolutely free from malaria. The serious symptoms which characterise it are the result of a profound intoxication acting more especially on the red corpuscles. The essentially malarial nature of this affection was till within the last few years admitted by all medical men who had practised in tropical countries. These observers invoked in support of their opinion the geographical distribution of hæmoglobinuric fever which has been observed only in parts of the globe where malaria prevails with intensity. At the penitentiary of St. Jean of Maroni (Guiana) after extensive turning up of the earth and clearing away of forests which produced a veritable explosion of malaria there were observed within two years 20 cases of bilious hæmoglobinuric fever with 16 deaths. Clinically the affection is related to malaria. Its appearance is always preceded by one or more attacks of fever of greater or less severity. Itself it constitutes only a more severe attack with the addition of a new symptom, hæmoglobinuria. This episode is followed in most cases by intermittent attacks as to the malarial origin of which there can be no doubt. Pathological anatomy also supports the identity of origin of these two affections. In both cases there is observed hypertrophy of the abdominal viscera and a quantitative,

and probably qualitative, change in the red blood corpuscles. It is true Laveran's hæmatozoon has not always been found in persons suffering from bilious hæmoglobinuric fever, but then these patients had taken quinine, the first effect of which is to cause disappearance of the hæmotozoon. In addition to malarial intoxication there are other causes which by increasing the energy of the poison or by supplementing it prepare the soil for the evolution of bilious hæmoglobinuric fever. Such is the influence of cold, of race, of constitution and foregoing pathological states. Attempts have been made to show that quinine intoxication plays a preponderant part in the etiology of bilious hæmoglobinuric fever. As a matter of fact in certain cases hæmoglobinuria has followed the administration of quinine, but as this was in persons affected with malaria it is more logical to refer the cause of hæmoglobinuria to the latter poison. Moreover there have been observed in Europe very marked cases of bilious hæmoglobinuric fever in subjects who had contracted malaria in tropical countries but who for a long time had taken no quinine. That drug is in daily use in the colonies, and in the vast majority of cases it acts powerfully on the malarial manifestations without causing the appearance of hæmoglobinuria. Quite recently it has been sought to show that bilious hæmoglobinuric fever is a special microbic disease—a sort of typhus having nothing in common with malaria. Yersin found in the urine of two patients a small bacillus which Bréaudad demonstrated to be the coli bacillus. Vincent has not found in the urine any pathogenic bacterium, nevertheless he admits the infectious and parasitic nature of bilious hæmoglobinuric fever as very probable. To sum up: there is no special bacillus, or at least none has been found. The prophylaxis of bilious hæmoglobinuric fever is the same as that of malaria. Attacks of the disease are more serious in proportion to the frequency of their repetition. Hence it is necessary that convalescents should leave malarial foci and return to Europe in order to avoid fresh attacks which often end fatally. Malarial subjects who are compelled to live in places where the disease is endemic must redouble their precautions to combat attacks and prevent their recurrence by the judicious use of quinine salts. All causes of chill should be carefully avoided.

---

(121) Etiology and Prophylaxis of the Hæmoglobinuric Attack.

DR. E. MARCHOUX said that of the authors who had given attention to the etiology of the hæmoglobinuric attack some considered the affection as one of the manifestations of malaria; others denied that it had any connection with that disease, and looked upon it as a substantive affection endemic in certain countries; while others again regarded it as the result of quinine intoxication. If the hæmoglobinuric attack were of purely malarial nature, it ought more frequently to be met with in the period when malaria is in the acute stage, when attacks are more severe, and the number of sufferers greater. But, on the contrary, it shows itself by preference after the bad season at the time when only chronic intermittent fever is observed. It is difficult also to explain, if the hæmatozoon is the only agent, why it never produces hæmoglobinuria in the first attack of fever, or why this symptom is so seldom seen in natives of the coast of Africa who are sometimes, especially in early life, as sorely smitten with malaria as Europeans. Lastly, if Laveran's parasite is the immediate cause of the hæmoglobinuric attack, it should be met with more easily in the blood of patients. Instead of regarding the hæmozoon as the cause, other observers look upon the affection as a special disease occurring only in certain regions, and as the result of certain influences. They base their view especially on the two facts that (1) the affection does not occur in all malarial countries; (2) quinine has no useful action in its treatment. It is the fact that hæmoglobinuria does not occur in all malarial countries, but it has been observed in all regions where malaria assumes the specially severe form met with in the tropics. Africa, which is the part of the world where malaria rages with the greatest violence, is also that in which hæmoglubinaria occurs most frequently. But it has been seen in the Antilles, in Central America, in Mexico, in Guiana, in Brazil, in the New Hebrides, in the islands of Polynesia, in Tonkin, in Cochin China, in Burmah, and in India. In Europe, it has been met with, though more rarely, in Sicily, in Italy, in Greece, on the banks of the Danube, and in the Caucasus. The bacillus found by Yersin in the urine has never been seen by anyone else. As for the parasites that have been described by certain authors occurring in the blood of sufferers from hæmoglobinuria they need not be more particularly referred to. The third opinion is certainly that which most satisfies the mind and is most in harmony with the facts. The experiments of Tomaselli, Carreau, Yersin and Dumas leave no doubt as the possibility of producing hæmoglobinuria by quinine. The cases in which that drug can be incriminated are now so numerous that they could not be counted. Among the reasons that have prevented investigators from universally attributing the hæmoglobinuric attack to quinine the following are the two chief: (1) Patients most frequently come to hospital with the hæmoglobinuria already established, and it is always difficult to get exact information as to its origin; (2) quinine given sometimes in large doses by way treatment has not prevented a certain number of patients from recovering. In point of fact quinine is not sufficient of itself to produce hæmoglobinuria. It is further necessary that the patient should be the subject of lesions generally of a transitory nature, but sometimes lasting, which favour the toxic action of the drug. Repeated and ill-treated attacks of fever are the most common cause of those lesions. It is after a more or less series of attacks of fever that one fine day after the administration of a dose of quinine hæmoglobinuria makes its appearance. Therefore, however paradoxical such reasoning may appear the best prophylactic means that can be employed to ward off hæmoglobinuria is the preventive use of quinine and the rational treatment of malarial attacks when, in spite of everything, they come on.

(122) Treatment of Bilious Hæmoglobinuric Fever.

DR. PAUL GOUZIEN, Médecin Principal des Colonies, presented a communication on the employment of large hypodermic injections of artificial serum and infusion of *Ahouandeme* (Cassia occidentalis, L.) in the treatment of bilious hæmoglobinuric fever. Since he has used injections of the physiological solution of sea salt (7 grams per 1,000) he has seen oliguria with alarming uræmic symptoms in only one case. Generally a dose of 100 to 300 grams at a time of this artificial serum is sufficient to stimulate and maintain the vital energy during the time necessary for corpuscular repair and the restoration of functional equilibrium. The injections should be repeated if need be. Dr. Gouzien has never found it necessary to go beyond four injections; sometimes one or two are sufficient. Dr. Gouzien's rule of practice is as follows: If at the end of twenty-four hours of hæmoglobinuria the urine shows no tendency to clear, and the temperature is not above 39° C., a first injection of 100 to 300 grams of artificial serum should be given in the thigh, and if necessary repeated on the following days. Each injection should last from five to fifteen minutes. Ordinarily it is well borne. In cases of moderate severity Dr. Gouzien also uses with advantage small enemata of the serum, of 200 grams each in the twenty-four hours. He has also employed with much success an infusion of *Ahouandeme*, the name given by the natives of Dahomey to the cassia occidentalis L. Whether the preparation acts solely by virtue of its diuretic, diaphoretic, and cholagogue properties, or whether it has a specific action on the pathogenic agent, is at present unknown. In some cases it acts almost at once, the urine clearing and being increased in quantity, with profuse sweating and copious stools, followed by rapid convalescence. The recognition of the good effects of the plant have led to its widespread cultivation in the colony. The following is the formula employed by Dr. Gouzien: *Ahouandeme* leaves, recently dried, 15 grams; infused in 950 grams of water. Filter and add juice of one small native lemon, and syrup 50 grams. A glassful to be taken at short intervals to a total amount of 1 to 3 litres in the day. From January, 1897, to the end of March, 1900, the number of patients treated by Dr. Gouzien for bilious hæmoglobinuric fever was 53 without a death.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF OBSTETRICS.

(123) Etiology and Nature of Puerperal Septicæmia.

M. Doléris presented a communication on this subject. He said the genius of Pasteur had determined the fact of the microbic nature of puerperal septicæmia, for we owe to him the notion of the existence, virulence, and contagiousness of the pathogenic puerperal germs. The ordinary pathogenic germs of puerperal septicæmia are:—The streptococcus pyogenes (the most common of all), the staphylococcus aureus, the gonococcus, the bacterium coli commune, etc. They are anaërobic or mixed. The search for anaërobic germs has led to the classification among the pathogenic agents of this order, in addition to the ordinary septic bacillus of the B. putridus, and some others less well defined. The conclusion is, therefore, that at the present time it must be admitted that certain anaërobic saprophytes can develop and act like true pathogenic germs, especially in the case of retained placenta. The association of different species appears to act more certainly in producing infection. The infection generally kills by toxæmia; the lesions also contribute to the production of death, notably in hyperacute peritonitis, by nervous inhibition or intestinal obstruction. The staphylococcus aureus may cause death by grave visceral metastases to the pericardium, pleura, kidney, etc. The demonstration of the pathogenic action of certain putrefactive saprophytes brings the discussion to the question of autogenetic infection. "Autogenetic" has recently received a special interpretation, according to which pre-existent pathogenic agents in the pathological vaginal uterine secretions should not be considered as saprophytes; and, since autogenetic infection is to be understood as depending on saprophytes, this comes to the same thing as denying their existence. This, said M. Doléris, is only an interpretation. From the clinical point of view one is bound to admit the reviviscence *in situ* of these pathogenic germs pre-existing in the uterine cervix and Fallopian tubes, and the possibility of such an infection becoming generalised after confinement without any fresh importation of pathogenic microbes from without.

(124) Etiology and Nature of Puerperal Fever.

Drs. Menge and Krönig, of Leipzig, said that under the name of puerperal fever was to be understood a disease following confinement in which pathogenic bacteria starting from the puerperal wounds produced during confinement injury to the organism. A rise of temperature above the normal point is unfailing. Among pathogenic bacteria it is not possible at present to distinguish between those which act solely in virtue of their toxic properties and infectious bacteria which have the property of penetrating into the tissues of the organism. It is likewise impossible at present to draw a distinction between a puerperal fever due exclusively to the absorption of bacterial toxins, and one resulting from the penetration of bacteria into the tissues of the organism The pathogenic bacteria that to day can be considered as capable of producing puerperal fever are: (1) Streptococcus pyogenes puerperalis, (2) staphylococcus pyogenes aureus, (3) gonococcus Neisser, (4) bacterium coli commune, (5) bacillus diphtheriæ, (6) diplococcus pneumoniæ, (7) certain bacteria, obligate anaërobes, but whose biological properties are not yet known. We may, nevertheless, regard these bacteria as pathogenic as they are found in the tissues of puerperal wounds. Neisser's gonococcus should not be excluded from the list of the pathogenic bacteria that must be taken into account when one has to do with puerperal fever. Puerperal infection caused by these bacteria may be heterogenetic or autogenetic. By autogenetic puerperal infection the authors understand an infection, produced by pathogenic bacteria that have lived in the condition of saprophytes before labour on the integuments of the external genitals or in the genital canal of the woman, and which, during confinement or immediately after it, invade the organism through the puerperal wound and set up disease. By heterogenetic puerperal infection they understand an infection produced by pathogenic bacteria carried by the air, by the instruments of the obstetrician, or by the hands of persons in attendance on to the puerperal wound and thence infect the organism. Gonorrhœal puerperal fever, having as its starting point a urethral, vaginal or cervical gonorrhœa, should not, any more than the infections of puerperal wounds proceeding from the blood or from infectious foci situated on the external and internal genital organs before confinement, be counted among autogenetic puerperal infections, because in these cases the infectious agent has not a saprophytic character. It is a case simply of the expansion of an infectious process pre-existent in the body. As the streptococcus pyogenes puerperalis, the streptococcus pyogenes aureus, the bacterium coli commune, the gonococcus Neisser, the bacillus diphtheriæ and the diplococcus pneumoniæ, do not live in the condition of saprophytes in the vaginal secretions of pregnant women, an autogenetic infection by those bacteria cannot have as a starting point the vaginal secretion of such women. An autogenetic infection produced by anaërobic bacteria of puerperal fever coming from the vaginal secretion is improbable. But still it cannot be absolutely rejected, because we have not yet succeeded in distinguishing the anaërobes of puerperal fever from the saprophytic anaërobes of the vaginal secretion of pregnant women in regard to their biological properties. Taking clinical facts as a guide, the authors regard as rare and as of favourable prognosis the autogenetic puerperal infection by pathogenic bacteria that have lived as saprophytes on the skin of the external genital organs. Pathogenic bacteria starting from the skin of the external genital organs may after confinement find their way even into the cavity of the puerperal uterus. An autogenetic infection produced by bacteria that have lived as saprophytes in the cervical canal, or in the cavity of the uterus, or in the tubes, can be absolutely rejected, for these organs never contain bacteria in the condition of saprophytes. Unlike autogenetic infection, heterogenetic puerperal infection is of the highest importance. Among the factors of an infection great importance must be attached not only to the virulence of the infectious germs and to the predisposition of the infected individual but also to the number of the infective agents. From this point of view the air, which is poor in germs, hardly plays any part in the production of a heterogenetic puerperal infection. When the obstetric instruments have been sterilised, the hands of the persons in charge of the confinement become the essential carriers of the infected agents. At the present day we are still met by insurmountable difficulties when we wish to determine the degree of virulence of the bacteria which play a part in puerperal fever. We can only consider it as demonstrated by experience that, as a general rule, virulence is diminished when the bacterium in question has long lived in the saprophytic state. Apart from general predisposition to puerperal infection, a local predisposition seems to exist in the case of insufficient hæmostasis in the genital passages or in the case of extensive lesions of the genital organs. The primary infective focus may be situated in the wounds of perineum, vagina cervix, and in the whole endometrium, remain localised there, or else spread by continuity or by metastatic infection. This extension most often takes place when the endometrium and the placental wound are affected. More rarely the infection starts from infected wounds of the cervix; most rarely of all it starts from infected wounds of the vagina and perineum. In the propagation of infectious microbes in the organism, the blood vessels and lymph canals are almost as often utilised. The streptococcus pyogenes puerperalis has the greatest tendency to overstep the limits of the primary focus. Nevertheless the majority of cases of infection by the streptococcus limit themselves to the endometrium and get well of themselves.

(125) Etiology and Nature of Puerperal Infections.

Dr. Pestalozza (Florence) proposed to

study the channels by which the different pathogenic agents could penetrate into the tissues of the genital canal of a lying-in woman and the conditions favouring this penetration. For this purpose he has analysed the results obtained in the Obstetrical Clinic of Florence during the five years 1895-1899, comprising a total of 4,015 women. This period was chosen because in 1895 disinfection of the vagina in a healthy woman in labour was for the first time abandoned. The clinic includes a lying-in department with an isolation pavilion for cases of puerperal infection. Here are received both women who have been delivered outside and developed symptoms of infection, and women who have become infected after delivery in the clinic. The lying-in department during the five years in question has admitted 3 847 women. Of this number, only 32 have had to be transferred to the isolation pavilion on account of infectious symptoms of any gravity, and these were for the most part women in whom labour had begun some time before admission. Of the 32, 30 were discharged cured; 168 women were admitted to the isolation pavilion after being delivered outside. Of these 25 died. The 3,847 delivered in the clinic were not subjected either to prophylactic disinfection of the vagina, or to vaginal or uterine injections after confinement, even in cases of artificial delivery. Those measures were reserved for very rare cases of women on whom suspicious manipulations or examinations had been practised before admission. The author's researches, clinical, anatomical, and bacteriological were made on the 200 women in the isolation pavilion. The results of these researches led him to the following conclusions: (1) The aseptic course of events following delivery depends on the rigorous application of procedures of disinfection of the external genital organs of the woman and of the hands and instruments of the obstetrician. (2) Disinfection of the vagina of a healthy woman in labour is to be condemned as superfluous and dangerous. (3) In cases where there appears to be justifiable doubt as to the asepsis of the vagina, that is to say, in women suffering from infectious diseases of the genital apparatus, the best thing to be done is to abstain from vaginal examination during delivery; (4) disinfection of the vulva and of the hands of the obstetrician is sufficient to obviate all possibility of infection during delivery; but there remains possibility of a puerperal fever arising from intoxication (sapræmia). (5) An antiseptic system properly managed should also include precautions necessary to limit the possibility of a putrid intoxication. That is to say, the prevention of premature rupture of the amniotic sac, the union by immediate suture of every vulvar, vaginal, or cervical wound, and especially careful assistance during delivery, no premature intervention being excluded. This is the best means of avoiding the retention of shreds of membrane, fragments of placenta and blood clots, which would present too favourable a soil for putrefactive processes. (6) After labour the practitioner should abstain from any vaginal or uterine injection. A large number of cases of infection must be referred to the imprudent use of these measures. (7) Should infectious phenomena show themselves, it is of the greatest importance to obtain an exact knowledge of the point of entrance of infection, that is to say, whether one has to do with a vulva, vaginal, cervical, or uterine infection, or a combination of these. The practice of forthwith having recourse in every case of fever to uterine injections is strongly to be condemned. There is reason to believe that they very often give occasion to extension of the infectious process. Especially in cases where there may seem to be ground for suspicion that the assistance has been imperfect from the point of view of antisepsis, one must always satisfy oneself as to the condition of the cervix uteri. Treatment of infection should also be preceded by careful diagnosis of the point of entry of the infection. This diagnosis in the present state of knowledge is of much greater importance from the practical point of view than the diagnosis of the nature of the infectious germs, a matter which is still surrounded by too many difficulties. (8) Bacteriological researches confirm the fact of the frequent occurrence of streptococcus infection. The streptococcus is the only agent which the author has been able to discover in cases of puerperal peritonitis or in metastatic foci. As for staphylococcus infection he has been able to find it only in the form of multiple abcesses in the substance of the uterus (cases of criminal abortion). Bacterioscopic examination is not always sufficient because there are forms of streptococci anaërobic in development that are often met with in forms of sapræmia, and which have not manifested any pathogenic property. The B. coli has not been found by the author except in cases of *intra-partum* fever arising from decomposition of the amniotic fluid. Lastly, there are cases that might seem to establish the possibility of diplococcic infection. In all probability, however, in such cases one has to deal with forms of sapræmia, or else the transport of decomposed fragments of the thrombus has prepared the soil for the growth of the diplococci which were on the wound.

---

(126) Conservative Treatment of Chronic Inversion of the Uterus.

Dr. Spinelli of Naples described (in the Section of Gynæcology) a conservative procedure which he said he had employed with success in the treatment of chronic inversion of the uterus. After disinfection of the vagina he seizes the inverted uterus and draws it towards the vulva. By a vertical incision he divides the anterior surface of the cervix and inverted body and by a transverse incision crossing the first he lays open the anterior *cul-de-sac*. By this means he gets two lateral flaps which give a large opening allowing the end of the inverted organ to be seized and reduced by traction from above downwards combined with pressure from below upwards. After reduction he sutures the anterior incision of the cervix and body, replaces the organ in the abdomen, and closes the anterior *cul-de-sac*. This operation, he says, is at once harmless, conservative, and effectual. It does not expose the patient to the risk of a backward displacement following a cure of the inversion, a condition which would frequently occur as a sequel of posterior colpo-hysterectomy.

---

(127) Treatment of Apparent Death in a New-born Infant.

Dr. Ribemont-Dessaignes said that during labour the child may suffer under the influence of numerous causes which need not be considered. Thus at birth it may present itself with the following marks of apparent death: Absence of cry, flaccid limbs, complete muscular relaxation while there is persistence of the heart beats, though sometimes very weak and at long intervals. Sometimes the cutaneous surface is bluish, violet, almost black; the face is swollen, the eyeballs project, and the conjunctivæ are congested; in fact, the child is in a condition of blue asphyxia. Sometimes, on the contrary, the skin is white, pale, discoloured, the mucous membranes are also whitish, the heart beats are imperceptible. This is what has been wrongly called white asphyxia. It is a syncopal condition. Lastly, in certain cases one meets with mixed forms, the characters of which are not sufficiently defined as to make it possible to label them either asphyxia or syncopal state. On the basis of this clinical description the author established the line of conduct to be followed in these different cases. In practice the asphyxial form is the most frequent. As it is due to obstruction of the air passages by mucosities or amniotic fluid loaded with meconium, it will be necessary first to clear the respiratory passages; secondly, to facilitate the entrance of air into the lungs in order to re-establish or regulate the cardiac and pulmonary functions. Very often the mucosities are only in the pharynx, and then a simple swabbing out with the finger wrapped in a piece of linen is sufficient to remove them and to induce the first inspiration. Skin frictions, either simple or with alcohol, ether, brandy, or eau de cologne, hot baths, mustard baths, baths alternately hot and cold, set up cutaneous stimulation which is often the starting point of a reflex action ending the production of respiratory movements. On this physiological principle rests the excitation of the pituitary, buccal, and pharyngeal mucous membranes. The method of rhythmical tractions of the tongue introduced by Dr. Laborde in 1892 has for its object the starting of the respiratory reflex. Very often the procedures that have been mentioned are not sufficient, and recourse must be had to artificial respira-

tion. There are numerous methods having for their object to cause the air to penetrate into the air passages: Mouth-to-mouth insufflation, Sylvester's method, and the methods of Schultze and Rivière. These methods fulfil only one of the two indications that have been laid down, namely, the clearance of the air passages and the facilitation of the entrance of the air. On the strength of these indications Dr. Ribemont-Dessaignes has been led to the conclusion that insufflation is the method of choice. The following principles have guided him in devising the instrument which bears his name: (1) The insufflation should be instrumental; (2) the apparatus used should make it possible to aspirate the mucosities; (3) it should introduce into the lungs only an amount of air proportionate to their capacity. Instrumental insufflation dates from last century, but Chaunier was the first to construct a tube penetrating directly into the larynx. The instrument was afterwards modified by Depaul, then by Pinard, but that tube still has many drawbacks. It is difficult to introduce into the larynx, it is easily displaced, it does not prevent the reflux of air, and does not indicate at each instant whether it has left the larynx and penetrated the œsophagus. With the object of remedying these defects Dr. Ribemont-Dessaignes thought that the tube should be constructed in accordance with exact anatomical facts. He therefore studied with care on frozen sections of bodies of newborn infants, on the one hand the bucco-laryngeal curve, and on the other the calibre and form of the interior of the larynx. The results obtained led him to have made a tube consisting of two parts. The first of these is formed of a conical portion which serves as a mouthpiece; on this can be placed a pear-shaped india-rubber ball of the capacity of 28 cm., having a perforation at the base. From the base is continued another portion also conical in shape. At the point of junction there is a double crown of pearls, the roughness of which gives a firm hold that prevents the instrument from rolling about between the fingers. The bucco-laryngeal part consists of a cylindrical buccal portion; it presents a double curve moulded on the projection of the alveolar edge and the concavity of the arch of the palate. The laryngeal portion has the form of a very short cone flattened on the sides and separated from a terminal knob by a circular constriction; on the concavity of the curve is situated an orifice for the escape of the air. When the instrument has been constructed exactly according to the pattern fixed on by the author in 1877, it presents the following qualities: (1) Its introduction is made easy by its curved shape and the arrangement of its terminal extremity; (2) the curve ensures its retention in the respiratory passages; (3) it prevents the reflux of air out of the larynx; (4) it makes it possible easily to aspirate the liquids and mucosities obstructing the bronchial tubes; (5) its proper position in the larynx or its introduction by mistake into the pharynx and œsophagus is at once indicated; (6) the india-rubber bag sends into the lungs only the quantity of air sufficient to indicate capacity. This obviates the danger of rupture of the pulmonary vesicles which are so fragile at birth.

DR. CHAMPNEYS (London) referred to the two stages of asphyxia (*a*) apoplectic or livid; (*b*) syncopal or pale, and described their mutual relations. The worst cases were common when the head came last; therefore the condition was not due to pressure on the head. Asphyxia was an exaggeration of physiological "air hunger," or "necessity for breathing." Remarkable instances were quoted of the survival of apparently dead children. The diagnosis of the stage of asphyxia was important—practically all serious cases were pale. Dr. Champneys laid stress on the uselessness of reflex stimulation in pale cases. The pupils were widely dilated in profound asphyxia, and they contracted on the re-establishment of respiration, but not of the circulation. The question of bleeding from the umbilical cord as a therapeutical method was considered. The objects of artificial respiration were: (1) Removal of foreign bodies from the air passages; (2) procuring the patency of the air passages; (3) excitation of the circulation; (4) ventilation of the lungs; (*a*) removal of foreign bodies from the air passages, by manipulation or by catheter; (*b*) procuring the patency of the air passages; the method of Schultze alone (of all methods by manipulation) favoured this; traction of the tongue did not directly raise the epiglottis; tilting up the chin was useless in children; bending the head backwards was useless for this purpose. (5) Excitation of the circulation was dependent on ventilation of the lungs; pressure on the precordia directly raised blood pressure. (6) For ventilation of lungs only two methods of manipulation were efficient—namely, those of Schultze and Silvester. The method of Silvester produced (unnatural) superior costal respiration, though the most powerful; the method of Schultze also caused descent of diaphragm. The methods of Marshall Hall and Howard were useless for children. Other methods were direct inflation of the lungs. The objections to mouth-to-mouth insufflation of air were (*a*) the danger of rupturing the lungs, (*b*) the danger of tuberculous infection, and (*c*) the danger of inflating the stomach.

PROFESSOR B. S. SCHULTZE (Jena) said the asphyxia of the newborn at the moment of birth was the result of an impediment to the placental respiration occurring in the course of labour. Paul Cazeaux was the first to enunciate this opinion in opposition to other doctrines which had previously prevailed. He said (in 1850): "In all cases the asphyxia of the newborn is evidently the result of the suspension of the placental respiration." The asphyxia of the newborn is, therefore, a kind of suffocation, the action of which may be interrupted, and which does not certainly cause death. The treatment consists in putting the pulmonary respiration in motion as soon as possible. Schultze emphasises the words "as soon as possible." Already in 1812 Legallois had ascertained the important fact that the younger an organism is, the better it can without perishing do without respiration. In many children born in a state of apparent death, the limit beyond which respiratory power will be lost is very nearly reached, and as long as the circulation goes on the blood becomes poorer and poorer in oxygen. The venous state of the blood, which is the ordinary stimulus to respiration, is in the child born in a state of asphyxia, already much above the normal standard: it no longer induces the medullary reflex. The medulla may still react under the influence of other irritations. For instance, one of the best stimulants is the effect of cold on the skin: a brief immersion up to the neck in cold water gives a better result, because it is more rapid than the rhythmical tractions of the tongue which have lately been suggested (Laborde). When the asphyxia has reached a still more marked degree, the medulla of the child no longer reacts. Then we must do all we can to re-establish the excitability of the medulla. This result can be secured only by bringing blood rich in oxygen to the medulla, and it can be brought only by way of the circulation. The object to be attained is then to re-establish the pulmonary exchanges, and to set in motion the blood in the vessels. By the insufflation of air many children born in a state of asphyxia have been brought to breathe regularly. In fact, after the first or second inspiration, the heart beats are a little accelerated; but, if the asphyxia is very deep, the heart speedily stops. The inspiration of air increases the pressure of the gases within the thorax as much as pressure made on the chest with the hand to imitate expiration. This procedure does not, however, make the circulation of the blood more active. The best procedures are those which, acting directly on the chest wall, induce marked and regular variations of the atmospheric pressure within the thoracic cage. Marshall Hall's method is of little use in the newborn child, because its thorax has its elastic equilibrium in the position of expiration. Silvester's method is very effective. Schultze's own "swinging" method brings about greater variations of atmospheric pressure in the thorax (25 c.cm. passed through the lungs at each inspiration in his experiments on still-born children). By such variations the pumping movements of the heart are immediately and energetically started. The difference of tension between the column of arterial and that of the venous blood is re-established, and the capillary circulation is thus set in motion. In this manner arterial blood is as rapidly as possible carried to the medulla, which thus recovers its excita-

bility, and becomes capable of obeying the call for breath. The following is Schultze's method of treating the asphyxia of the newborn: (1) If the child is of a reddish-blue colour, if there is still some tension of the muscles, it should be left in communication with the umbilical cord as long as any heart-beat is perceptible. Mucosities must be removed from the mouth, and the skin reflexes must be excited. If it does not react immediately the cord should be cut, and the child should be plunged rapidly and for a very short time into very cold water, then placed in a hot bath. These immersions should be repeated till the child cries lustily. (2) If the child's body is pale and flaccid, like a corpse just after death, one need not expect any result from excitation of reflexes, and precious time will be lost by attempting to provoke it. The cord should at once be divided, the mucosities should be removed from the mouth and pharynx by pulling forward and pressing the base of the tongue so as to raise the epiglottis, and artificial respiration either by Silvester or by Schultze's method. In the latter case the treatment should be begun with a prolonged expiration "swing." There is no better way of emptying the bronchi of mucosities. After making the child pass from the position of expiration to that of inspiration eight or ten times in a minute, it should be put into a hot bath and watched, when it will be seen that the heart-beats become stronger and more frequent, the skin becomes red, and muscular tension reappears. If the treatment is not speedily successful the child should be again "swung" after the bath. The expiration movement usually produces the first spontaneous inspiration, then the child is immediately put into a hot bath. If, nevertheless, the respiration continues to be shallow the child should be plunged into iced water. It reacts at once, strongly flexes the thighs, and cries lustily; the medulla now responds to excitation of the reflexes. A child born in a state of asphyxia should never be looked upon as completely restored till it cries continuously and loudly.

DR. AUDEBERT (of Toulouse) stated that he had tried artificial cooling for the resuscitation of asphyxiated children with the best results.

DR. LEPAGE (of Paris) said that recently rhythmical tractions of the tongue had been proposed as a substitute for insufflation, but he was of opinion that the former was much superior to the latter method. He had never been able by tractions of the tongue to reanimate a child when artifical restoration had failed.

DR. WALLICH (of Paris) said that when the bodies of newborn infants that had presented the phenomena of apparent death were examined *post mortem*, more or less extensive visceral lesions, hæmorrhagic or other, were often found. From this he drew the conclusion that it was important that manipulations for the purpose of recalling these children to life should not be too violent, and he thought that artificial insufflation with the aspirating and inspirating tube was in this respect preferable to the large swinging movements recommended by Dr. Schultze.

DR. DRAGHIESCU described the technique employed in the maternity hospital of Bucharest in the serious cases in which pulsation was no longer perceptible in the cord. After having cleared the upper air passages by means of a little sterilised swab rolled round the forefinger, an elastic catheter slightly curved and perforated at the end was introduced into the larynx. The mucosities and foreign substances which the child might have swallowed were withdrawn by aspiration. When this was not sufficient artificial respiration was performed in the following manner: After mouth-to-mouth insufflations, light pressure was made with the hand now on the belly, now on the chest, imitating the movements of inspiration and expiration. Insufflation could often be made with advantage by means of a ball of oxygen.

DR. RAPIN (of Lausanne) found that pressure on the chest was sufficient to clear the air passages of mucosities, and he had found the manipulations recommended by Schultze very successful.

DR. STRATMANN (Solingen) said he had been able by means of manometric instruments to assure himself that Schultze's method gave the largest amplitude of respiratory movements.

DR. VERRIER (Paris) said that without having recourse to the wide swinging movements involved in Schultze's procedure he used extensive movements of raising and lowering of the arms, which seemed to be equally successful in producing dilatation of the chest with less violent shaking.

DR. DEMELIN (Paris) said that comparisons had been instituted between the method of tractions of the tongue and of insufflation greatly to the advantage of the latter procedure. He remembered having seen M. Tarnier use both methods side by side. When after having insufflated the child and thus obtained a return of almost regular heart beats, with gasping inspiratory movements, the artificial respiration was given up and tractions of the tongue practised, the inspiration became less frequent, and the heart beats progressively weaker. On recommencing artificial respiration the condition of the child again improved. Dr. Audebert's experience of the beneficial effects of cooling did not agree with that of the majority of obstetricians, who rather dreaded the effect of cold. A distinction must be drawn between cases of livid asphyxia, which might be benefited by swinging, and those of white syncopal asphyxia dependent on cerebral and bulbar injuries, against which the practitioner was almost powerless.

PROFESSOR PINARD said that in the case of children born in a state of apparent death the practitioner must strive to restore respiration and circulation. To attain this object he found himself in contradiction with the physiologists in preferring artificial respiration to methodical traction of the tongue. For the performance of artificial respiration they had the method of manipulation, one of the types of which was Schultze's procedure and the laryngeal tube. External manipulations did not generally succeed in emptying trachea and the bronchi; with the tube it was easier to clear the air passages. Schultze's method, if a little brutal, exposed the child less to the risk of pulmonary emphysema.

DR. CHARLES confessed that he did not find the method of mouth-to-mouth aspiration at all bad. As regards mucosities, the greater part might be expelled by pressure on the chest.

---

(128) Asthma and the Puerperium.

DR. AUDEBERT said that common asthma like hay-asthma sometimes appeared during pregnancy. It might also manifest itself only during gestation, and become a true sign of pregnancy. Halliday Croom had published three cases and Chambrelent two others. Adding to these five two cases observed by himself, he had, from a study of the course of this complication, been led to the following conclusions: the disease redoubles in intensity during pregnancy. At the time of confinement the attacks are especially violent and dangerous. The prognosis is serious for the mother (one death in seven cases), and especially for the child (two deaths), which shows manifest signs of suffering during the paroxysms. Contrary to what might be supposed, the difficulty of breathing, even when very intense, does not produce contractions of the uterus, although the suffocation should cause an excess of carbonic acid in the blood. As regards the etiology of such attacks of asthma during pregnancy we are reduced to hypotheses. Is it the embarrassment of the lungs by pushing up the diaphragm that must be, or is it irritation of the pneumogastric? Or else have we to do with a kind of menorrhæmia, that is to say, poisoning of the blood in women in whom the periods have been suspended as the result of conception? Whatever may be the pathogeny of the affection, the treatment which Audebert has found most efficacious is the use of morphine and quinine. From an obstetrical point of view it is important as soon as possible to withdraw the child from the influence of the maternal crises by premature delivery, induced at a fitting time and speedily terminated.

OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF PSYCHIATRY.

(129) The Psychoses of Puberty.

PROFESSOR MARRO (Turin) summed up the results to which his own researches and experiences had led him in the following conclusions: (1) Puberty exercises a notable influence on psychical life which manifests itself either by giving to pre-existent mental disorders characters which they had not formerly or which they had in a lesser degree, or by opening the way to the onset of psychoses. (2) Among the psychoses that may attack boys and girls at the period of puberty there is one in particular, the hebephrenia of Hecker, that may be regarded as specific, inasmuch as in it are combined the several characters which it shares with other psychoses. (3) The morbid manifestations of this particular form of psychosis and the changes found on necroscopic examination show that the cerebral cortex and the meninges are the seat of a morbid anatomical process. The symptoms of invasion tend to prove that its source may with a certain probability be found in a process of auto-intoxication, caused by disorders of the digestive apparatus. (4) From the period of puberty and the premature and abnormal exercise of the generative function, other morbid manifestations take origin. The influence of these impresses a peculiar stamp on the character of the individual which is permanent in nature, though age and favourable conditions of life may obliterate the evidence of it. (5) The prophylaxis of the mental disorders requires that the greatest care should be taken to avoid all causes of weakening that may interfere with the development of the mind and body at this most important period of life, such as overfatigue, physical or intellectual, and above all precocious and abnormal sexual indulgence.

DR. JULES VOISIN, Physician to the Salpêtrière, said that all authors had considered puberty to be an important cause of insanity. Pinel, Esquirol, Marc, Spurzheim had particularly called attention to the subject, but in their view the psychoses of puberty did not constitute a morbid entity. It was Kahlbaum in 1863, and his pupil Hecker in 1871, who first described under the name of "hebephrenia" or insanity of youth a distinct affection having its own characters and course. They placed it in the class of paraphreniæ that is to say, psychoses connected with a phase of physiological evolution. Soon these authors perceived that hebephrenia presented two different forms: A serious one to which they reserved the name "hebephrenia," which terminates in a profound dementia; and a slight form to which they gave the name "heboid" or "heboidophrenia," which terminates in arrest of intellectual development approximating to imbecility. Numerous writings have appeared on the subject, both in France and elsewhere. While Kahlbaum considered hebephrenia to be independent of hereditary taint, Krafft-Ebing, Sterz, Finck, Kovalewsky, Thomas Clouston, Maichline, Serbsky, Morel, Lagnan, Legrand, du Saulle, Falret, Regis, Joffroy, etc., regarded it as being either due to a disease inheritance or as a result of acute psychoses of infancy. Almost all these authors agree that most psychoses which develop during puberty, and especially at its commencement, got well without leaving any trace, and that among demential psychoses there was a dementia in all points resembling the progressive general paralysis of the adult with the exception of the ambitious delirium. It was therefore necessary to admit several varieties of psychoses of puberty and the puberal evolution was not the only cause. Whether one invokes the theory of reflex cerebral excitation or the theory of glandular secretion it is certain that other elements enter into its causation. First of all what is puberty? What are the limits of that period? Puberty is not only characterised by sexual maturity but also by growth of the body, development of the intelligence, and the appearance of new sentiments having relation to that maturity. The period of puberty, which extends from 12 or 14, according to sex, race, or climate, up to 22 years, comprises diverse physiological acts, which may be arrested, disturbed, or perverted in their evolution by infinitive causes physical or pathological. These causes have an influence all the stronger when they act upon a predisposed subject. Painful menstruation, which undermines the nervous system; over-abundant menstruation, which depresses it; too rapid growth; defective or insufficient nutrition; work, physical or intellectual, that is too prolonged or above the strength of the subject: an infectious illness, a moral or physical shock, play the principal determining part in the great majority of cases. Grave conditions of dementia appear to be caused rather by these causes than by the on-coming of sexual life. In most young girls the appearance of the menses causes no mental disturbance and passes unperceived. If mental disturbance does occur, it generally does not last long, and shows itself only in persons with a marked hereditary predisposition. A prepared soil is therefore necessary for the development of the psychoses. But the indispensable element is heredity. Puberty and all debilitating causes or illnesses of that period are only secondary. The combination or symptoms presented by the psychoses of puberty is a further proof of the important part played in these affections by heredity: alternations of excitement and depression, periodicity of symptoms, impulsive paroxysms. These disorders are very variable, having sometimes the form of a pure psychosis, sometimes that of a mental regression or degeneration, sometimes that of a neuropsychosis, sometimes that of a toxic delirium. Dr. Voisin proposed the following form of classification:—1.—Pure psychoses of puberty: (*a*) Melancholia (simple passive melancholia; active melancholia with excitement, melancholia with stupor, catatonia); (*b*) mania (simple mania, typical form, rare in adolescence; irritable mania, simple choreic mania with hallucinations; catatonic form); (*c*) mental confusion; (*d*) hallucinatory insanity. 2.—Regressive states: (*a*) dementia of puberty; hebephrenia, acute or primary dementia; acute stupor; (*b*) early simple dementia; (*c*) progressive general paralysis; (*d*) epileptic spasmodic dementia (see epilepsy). 3.—Mental degeneration: (*a*) paranoia; (*b*) periodic insanity; (1) intermittent and (2) circular or double form; (*c*) phobias, obsessions, insanity of doubt and of touch; (*d*) kleptomania, dipsomania; (*e*) sexual aberrations; (*f*) impulses; suicide; homicide; (*g*) moral insanity; (*h*) delirium of degeneration. 4.—Combined psychoses: (*a*) neurasthenia; (*b*) hypochondriasis; (*c*) hysteria; (*d*) chorea; (*e*) epilepsy (1) chronic psychosis, spasmodic dementia; (2) acute psychosis. 5.—Psychoses from intoxication: (*a*) infectious autointoxication; (*b*) alcoholic intoxication. Dr. Voisin formulated his conclusions as follows: (1) By psychoses of puberty are to be understood mental affections developing during the period of puberty, that is to say from 12 to 14 to 22 years of age. This period is characterised by sexual maturity and the physical and intellectual development of the individual. (2) All varieties of psychoses may show themselves at this period. Hebephrenia does not exist as a morbid entity: the term should be reserved for cases of dementia. Psychoses which develop at the commencement of puberal evolution are less grave than those that show themselves during the course or towards the end of puberty. The former may be called psychoses of puberty; the latter are psychoses of adolescence. (3) Hereditary predisposition is the predominant cause of these affections. It is the association of incomplete intellectual development with hereditary taint that gives the disease its "hebephrenic" stamp. (4) Pure psychoses, or more properly those that most approximate the pure forms, present atypical mixed forms which in the majority of cases get well. (5) Melancholia most often appears under the grave form of stupor, being accompanied by impulsive acts, obsessions, and imperative hallucinations directed against the life of the patient and those about him. At the same time very often mysticism and onanism are observed. (6) Mania is seldom present in the benign form. It

most often takes the character of moria, and also presents many impulsive elements. (7) The early dementia (hebephrenia) described by Kahlbaum and Hecker occurs in two forms—a grave and a slight one. The grave form may present the symptoms of stupor dementia, catatonia, and mental confusion. This makes the diagnosis difficult. The light form or early simple dementia (one of the stigmata of mental degeneration, Morel) must be distinguished from progressive general paralysis and spasmodic epileptic dementia. (8) Mental confusion represents a delirium of dreaming which has much analogy with alcoholic delirium. This oneiric delirium is the characteristic of the psychoses of auto-intoxication, and it is almost certain that disorders of nutrition in adolescence are the causes of this delirium. Recovery takes place in one half of the cases. It is generally announced by crises, sweats, diarrhœa, salivation, menstruation, abscesses, boils, etc., and retro-anterograde amnesia is almost always observed as in cases of polyneuritic psychoses. (9) Juvenile progressive paralysis is distinguishable from the same disease in the adult by the absence of ideas of grandeur and ambitious delirium, and by its slower course. Many authors attribute its causation to hereditary syphilis. (10) Degenerative psychoses and neuropsychoses are the most frequent. They generally reappear in adult age. (11) From a medico-legal point of view psychoses of puberty are subject to the same rules as those relating to adult life, except in regard to civil capacity, since the French law recognises no civil capacity under the age of 21 years. Criminal responsibility, which is fixed at the age of 16, has, of course, to be taken into account.

Professor Ziehen (Jena) said that from a study of some 400 cases of mental diseases, the first symptoms of which showed themselves at puberty, that is to say from 13 to 21, he had come to the following conclusions: (1) Mental morbidity is at one of its maximum points at puberty; heredity gives a much larger morbidity at that period, and in addition anæmia, over-work, physical and intellectual, acute infectious diseases, and sexual excesses play an important part in the etiology of the psychoses; (2) almost all known psychoses are met with at puberty. A special influence due to that period shows itself only in this that certain psychoses are very prevalent, while often, but by no means always, mental maladies at that time undergo certain special modifications in their symptoms and course. It is, therefore, in error that certain authors have spoken of a special psychosis of puberty which should include the majority of cases of mental disease occurring at that time of life. The one psychosis which belongs almost exclusively to puberty—the hebephrenic dementia or hebephrenia of Kahlbaum—contributes a relatively small number of cases to the sum of the psychoses of puberty; (3) the psychoses prevalent at that period apart from hebephrenia are the following: *Folie circulaire*, mania, melancholia, acute hallucinatory paranoia (the amentia of certain authors), and insanities of hysterical and epileptic bases. (4) The most important modifications produced by puberty are the following: Exaggerated weakness of effective disturbances ("affective dissociation"), want of harmony between these disturbances and mimic reactions ("hebephrenic paramimia") in coherence not only in delirious ideas but in normal thought, a tendency to mimic verbal, etc. stereotypes, illogical, trivial, and fantastic character of the delirious ideas and tendency on the one hand to a circular course, on the other to progressive dementia. All these modifications are met with in some psychoses of puberty more often than in others: (5) the prognosis is, owing to the changes just indicated, in general worse than in post-puberal psychoses; (6) the treatment does not in general differ from that of post-puberal psychoses. Total confinement to bed is indicated only in cases where there is great exhaustion. Regular occupation both of body and mind fixed for every hour of the day is of particular importance in the majority of cases. The use of narcotics should be restricted as far as possible. Great care is required in the selection of the adult patients with whom those at the age of puberty are placed in the same ward.

---

(130) Rest in Bed in the Treatment of Acute Forms of Insanity.

Dr. Clemens Neisser (Leubus) introduced a discussion on rest in bed in the treatment of acute forms of insanity, and the modifications which it may bring about in the organisation of institutions for the reception of lunatics. He said that by the introduction of rest in bed into the treatment of mental diseases the principle that lunatics should be dealt with as persons suffering from disease had been irrevocably admitted. A distinction must be made between confinement to bed applied to special cases, and the same measure employed as a general system of treatment. Dealing with the latter first, Dr. Neisser said: (1) It is a general principle that for all individuals whose attitude and conduct are disorderly, excited, or merely strange, whether one has to do with maniacs, melancholics, subjects of hallucinations, patients suffering from methodical delirium, epileptics, general paralytics or dements, the best treatment is confinement to bed. Of course, the physician may, if he thinks proper, allow the patient to get up in order to take his share in work, amusement, walks in the garden, or meals in common; but stupid standing about, lounging and clustering in corridors and day rooms must be strictly forbidden and replaced by bed. (2) The patient should be put to bed immediately on his arrival, or rather after the bath, which should be the first part of the treatment. As it is indispensable that the patient should be in bed for the first medical examination, no special indication for this is necessary. In other words, bed is the treatment naturally called for; it can be dispensed with, temporarily or definitively, only in special cases as enjoined by medical order. (3) Confinement to bed facilitates the necessary supervision and care, which in certain cases would be impossible without it; therefore, for this reason and in the general interest, it may also be indicated in the case of patients recognised to be incapable of undergoing direct therapeutic action (either at first or in the course of the malady). With regard to confinement to bed as a special treatment, Dr. Neisser said: (1) It is not a specific treatment of mental affections any more than of fevers or wasting diseases. It is only one of the means of treatment which must be suitable for the case and for the individual. Confinement to bed, the most simple, natural, and general therapeutic measure to sufferers from mental disease, has been regarded as something almost new and special; but this is not so. (2) Confinement to bed meets only one therapeutic indication, rest for the brain, using this term in a physiological sense as opposed to psychical suggestions. (3) It is therefore indicated in all cases where it is necessary to act against symptoms of irritation, first of all in all diseases of acute type. (4) The individual mental condition must be taken into account, especially by placing and grouping the patients in a judicious manner either in one of the common wards or in separate rooms, the door of which may be open or shut but under constant watch. The most precise individualisation is an absolute necessity in this matter. (5) On the one hand, as long as an acute condition of illness exists, the essential part of the treatment is physical rest, that is, rest of the diseased organ. On the other, as soon as the acute symptoms begin to disappear without there being any tendency to recovery, treatment should be directed to the conservation and quickening of the remains of the psychical personality by imposing on the patients occupations for that purpose starting from a given moment. That moment is not easy to determine. If it be allowed to pass, the patient easily falls into the "bed mania"—a mania difficult to combat, and which is hurtful both to his physical and moral constitution. It is therefore advisable, sometimes even in the acute stage, to combine confinement to bed with work and exercise in the open air. This may be done in several ways (occupation in bed, alternation of rest and work, or of walks, mixed system of Toulouse). In the majority of juvenile mental affections, confinement to bed should not be too much prolonged. As regards the modifications in the organisation of establishments for the insane necessitated by the treatment, Neisser said: (1) Confinement in bed does not necessarily involve considerable changes in construction, and can be carried out in old institutions; as a proof of this, he cited the plans of Leubus. (2) There should be no sections comprising only

separate cells, except in asylums for criminal lunatics. (3) It is desirable to have as many sections as possible, not too large or varied. Given mixed asylums for curable and incurable cases of medium dimensions, they should be allocated in the following proportion: For every 100 patients two or three sections, each containing about 20 beds. Each of these sections should comprise three or four rooms of different size, and agreeably furnished for patients warded together, a common day room, and three or four separate rooms. The rooms should be arranged in such a fashion that an efficient watch can be kept by a small number of attendants. 4. Each section should contain what is needful for baths. 5. There should be 100, at most 200, patients for each physician, even if the inmates do not change frequently, otherwise the treatment is difficult to carry out. 6. The treatment involves an increase in the number of attendants only if their time of duty is shortened and they are more frequently replaced. It is evident that in looking after patients actively an attendant becomes more fatigued than in watching persons shut up in cells or perhaps chained. 7. The attendants must of course be under the direction of the physician. 8. By confinement to bed in wards room is gained, separate sleeping rooms being no longer required for many patients. 9. Statistics collected at Leubus showed that the bed treatment is, from the administrative view, productive of economy in the matter of clothing.

PROFESSOR S. S. KORSAKOFF (Moscow) said: (1) We must distinguish between confinement to bed as a system of internal organisation of asylums and its use as a therapeutic method. (2) The bases of the system are as follows; (*a*) Bed is considered as an essential element of the treatment; (*b*) stay in bed is secured not by violence but by means of the moral effect and suggestive influence of the environment; (*c*) the attendance must be organised in such a way that it shall be a means of nursing the patients and carefully observing the physical and psychical symptoms of the disease. One of the principal advantages of the system is the diminished use of cells. (3) The exact apportionment of the time to be spent in bed, in walks, and in occupations out of bed, is the essential part of the system. The treatment should be regulated in all its details, from absolute confinement to bed to the most limited stay there. (4) The use of common wards is a potent means of help in the regular organisation of the system, although it may be necessary to apply it also in separate rooms. Confinement to bed by force is not an element in the treatment. (5) The chief advantages of the system are: Better order in the asylum, especially if it is crowded; greater safety for the patients; greater facilities for nursing and for clinical observation; less use of separate rooms; the system may make it possible to dispense entirely with confinement in cells. Mental diseases characterised by excited states run a milder course in asylums where the system of bed treatment is carried out; the mortality of some grave acute psychoses is notably diminished. (6) In addition to confinement to bed, other systems which act favourably—such as the moral influence, no restraint, work and open-door systems—must not be neglected. A happy combination of these is perfectly feasible. The quietism which sometimes becomes developed in the medical staff of an asylum under the influence of the bed treatment is mere abuse. (7) The indications for absolute rest are only imperfectly established. Before they can be placed on a scientific footing it will be necessary to make not only further researches, but to widen their scope. Points deserving of study are: The effect of the rest in bed and of the want of exercise on the composition of the blood, the elimination of toxins, and on the psychical functions, especially on the energy of the directing apparatus of the mind (apperception). (8) The principal indication for confinement to bed is a condition of excitement. It should not be too long or too rigorously applied in patients of inactive intelligence, predisposed to apathy, anæmia, and masturbation. It is very important that the effect of this treatment in the mental diseases of young persons should be particularly studied, especially in relation to their becoming incurable. (9) The treatment should be applied in a different manner according to individual indications in almost all psychoses acute in form, especially in the initial stage of the disease. Its action is particularly favourable in most patients suffering from mania and alcoholic delirium, and in many forms of mental delusion and melancholia. There may be special indications for its use in cases where the mental disturbance is connected with an infection, a high temperature, or great exhaustion.

DR. JULES MOREL (Mons) presented a communication the conclusions of which may be summed up as follows: I. Every lunatic admitted into an institution should first be placed in the observation quarter for thorough examination, physical and mental. II. Confinement to bed should be employed in the following cases: (1) All cases of acute or chronic psychosis presenting intercurrent conditions of excitement and depression; (2) all in which there is any disturbance of the general nutrition; (3) all cases of patients incapable of behaving in accordance with the rules of ordinary life—those that are mischievous or refuse their food or show suicidal tendencies, etc.; (4) all cases in which there exists a complicating somatic affection of any gravity. III. In order that the object of the bed treatment may be satisfactorily attained, it is necessary (1) that the institution should have a competent medical staff proportionate to the requirements of the service; (2) that the various physicians attached to the institution should live in it and have each a real share in the observation and treatment of the patients; (3) that no means of restraint should be used except in very rare and exceptional cases; (4) that the medical staff should undertake the professional instruction of the attendants and eliminate from among them all who are not entirely satisfactory; (5) that the staff of attendants should be composed of intelligent persons of irreproachable morals sufficiently paid and having the prospect of a retiring pension after a certain number of years of service; (6) that the buildings and their offices should satisfy all requirements as regards comfort both for the patients and the staff.

---

(131) The Pathological Anatomy of Idiocy. DRS. G. E. SHUTTLEWORTH and F. BEACH presented a communication on this subject. They said that as far back as the time of Hippocrates the physical characteristics of idiocy were noticed. In the first volume of the English translation he speaks of the Macrocephali, who were in the habit of producing cranial deformations of the head. Pliny, too, in his *Historia Naturalis* mentions the Macrocephali, and Tulpius (*Observationes Medicæ*) has a chapter on hydrocephalus, which he had seen associated with idiocy. Willis, in his *Collected Works* in the part dealing with the anatomy of the brain (English edition) describes and figures, the brain of a young man, completely imbecile, the size of whose brain was scarcely one-fifth of that of an ordinary man (microcephalus.) Pinel (*Traité sur l'Alienation Mentale*) also describes and gives illustrations of two cases of microcephalus, and Gall and Spurzheim in their atlas accompanying their *Anatomie et Physiologie du Système Nerveux en Général et du Cerveau en Particulier* give plates not only of microcephalic heads and crania but of hydrocephalic crania, in one case of a cretin in the other of an imbecile child. The above remarks have reference to the size of the head. As regards the form, bony deformations are noticed by Meckel in *Mémoires de l'Académie de Berlin* published by him in 1760. With respect to conformation Tulpius (*Observationes Medicæ Rariores*) remarks that the convolutions are less numerous, and Malacarne (*Encephalotomia nuova universale*) states that the lamellæ of the cerebellum increase or diminish according to the development of the intelligence. As regards the organisation, Meckel (1760) remarks that in idiots there are dryness and hardness of the cerebral substance, and Bonnet and Haller report tumours and ulcerations in the brain and cerebellum. Finally, Esquirol (*Des Maladies Mentales*) notices that the convolutions are small, atrophied, compact and thin, and that the lateral ventricles are of small capacity. Apparently the first observers dwelt most on the size and shape of the head as causes of idiocy, the structure of the brain being noticed at a later period. Coming now to recent times, modern authors are of opinion that pathology and classification are mutually interdependent. According

to this view, Drs. Shuttleworth and Beach have classified the anatomo-pathology of idiocy under three chief heads—namely, (1) congenital formative defects; (2) developmental cases; and (3) acquired cases. Under the first head they place (1) microcephalus; (2) hydrocephalus; (3) scaphocephalus; (4) Mongol imperfections of the osseous, cutaneous, mucous, and in some cases cardiac tissues; (5) neuropathic *genetous* cases, in which the convolutions are coarse and simple, or are small, slender, and curling (mycrogyry); (6) amaurotic *genetous* cases; (7) sporadic cretinism, due to defective structure or absence of the thyroid gland; and (8) partial local defects, such as defect of the corpus callosum, or porencephalus. Under the second head they include (1) eclamptic cases, with hæmorrhagic or inflammatory lesions; (2) epileptic cases: (3) syphilitic and juvenile general paralysis cases; and (4) paralytic cases, in which there are degenerative changes in the vessels of the brain, or in some cases atrophy of the brain. These cases may be due to birth palsy, to palsy coming on after whooping-cough, or to inflammation. Under the third head are comprised (1) traumatic cases, due to pressure on the head during labour, owing to abnormal narrowness of the pelvis, prolonged labour, or less often the use of the forceps, and lesions produced by accidents; (2) post-febrile inflammatory cases; under this sub-head is placed hypertrophic idiocy, a monograph on which subject has been published by one of the authors; and (3) sclerotic idiocy, a disease first described by Bourneville in 1832. The changes in the brain observed in this disease were noted by Dr. Wilmarth in 25 out of 100 cases, and have been frequently noted by Beach, who not only described the changes already observed, but also hyperæmia, softening, tumours, and disease of the membranes of the brain; asymmetry of hemispheres and convolutions; alteration in relation of grey to white matter of brain; simplicity of convolutions, thickening of the arteries, thrombosis, disease of the cerebellum and spinal cord; and anomalies of the convex surface and base of the cranium in Tuke's *Dictionary of Psychological Medicine*, 1892. The microscopical appearances of idiocy have been observed and noted by one of the authors, and by Bevan Lewis, Andriezen, Mierzjewski, Hammarberg, Bourneville, and A. W. Campbell. A beautiful series of drawings by the last-named, illustrating microscopical appearances observed by him in five brains of idiots was shown to the Section.

Dr. Bourneville said that as the result of researches pursued during twenty-five years at the Salpêtrière, and especially at Bicêtre and on the communications which had been published during the same period on idiocy, or to speak more accurately on the various forms of idiocy, he had been led to distinguish up to the present, from the anatomo-pathological point of view, the following forms: 1. Idiocy symptomatic of chronic meningitis (meningitic idiocy). 2. Idiocy symptomatic of chronic meningo-encephalitis (meningo-encephalitic idiocy). 3. Idiocy symptomatic of arrested development of the convolutions without malformations, with lesions of the nerve cells (congenital idiopathic idiocy). 4. Idiocy symptomatic of hypertrophic or tuberous sclerosis. 5. Idiocy symptomatic of atrophic sclerosis, (*a*) sclerosis of a hemisphere or of both hemispheres of the brain (hemispheric or dihemispheric sclerosis); (*b*) sclerosis of a lobe of the brain (lobar sclerosis); (*c*) sclerosis of separate convolutions; (*d*) shagreen sclerosis of the brain? 6. Hemiplegic or diplegic idiocy, symptomatic of focal lesions due to vascular obliteration or to hæmorrhage (pseudo-porencephaly, etc.). 7. Idiocy symptomatic of simple ventricular hydrocephalus or complicated by extraventricular hydrocephalus (hydrocephalic idiocy). 8. Idiocy with pachydermic cachexia or myxœdematous idiocy associated with absence of the thyroid gland. 9. Idiocy symptomatic of an arrested development of the brain with congenital malformations (true porencephaly), absence of corpus callosum, etc. 10. Idiocy symptomatic of microcephaly from arrest of development with or without malformations or having for cause lesions occurring after birth (microcephalic idiocy properly so-called or symptomatic). Dr. Bourneville has seen no case of idiocy that could be referred exclusively to an osseous lesion, in particular to premature synostosis of the bones of the skull.

Dr. Mierzejewski, formerly Professor of Clinical Psychiatry at St. Petersburg, said that the classification of the various forms of idiocy proposed by Dr. Bourneville answered the practical needs of science in its present state, but with the progress of knowledge an anatomo-pathological classification based on the study of the delicate nervous structure and its elements, and on exact embryological data will become necessary. The basis of all anatomical lesions in the brains of idiots is a deviation of development of the nervous tissues; its origin must be sought for in embryonic life or in the pathological lesions which are produced in earliest infancy, and are the starting point of later deviations of development. There is no true arrest of development in a morphological and histological respect affecting the brain as a whole, but there is a true arrest of development of certain regions of the brain tissue which may be recognised by the presence of neuroblasts. Among the brains of idiots belonging to this category, which from their special characteristics may form a group apart, are those in which the white matter of the cerebral hemispheres is very slightly developed, whilst the grey matter of the cortex is distinguished by its prodigious abundance. These brains, which belong to microcephalic and demi-microcephalic idiots, have most often microgyric convolutions, but this may be absent. The brains of such idiots are characterised by very slight development of the centrum semi-ovale, and by the enormous distension of the ventricles, the cerebral hemispheres becoming transformed into bladders with thin walls. There is a special type of microcephalic brain characterised by richness of grey matter and insufficient development of white matter and by microgyry. This type is distinguished from the ordinary type of microcephalic brain by the fact that in the latter, with general diminution of the nervous tissue of the hemispheres, the corresponding proportions between the grey and the white matter are maintained. After this special type peculiar to certain microcephalic brains come certain demi-microcephalic brains in which arrest and development of the white matter attain a less high degree, and are accompanied by diffuse subcortical heterotopia of the grey matter. In both cases the type remains the same, and its special character consists in this—that between the grey matter of the cerebral hemispheres and the centrum semi-ovale the nervous tissue is sometimes found in a state of true arrested development, as proved by the presence of neuroblasts, and in other cases in a state of deviation of development which manifests itself by the presence of elements resembling the ganglionic cells of the deep layer of the cortex. The examination of brains of idiots proves that abundance of grey matter and of nerve cells may be accompanied by idiocy, but in such cases the system of connections between the convolutions is arrested in its development, and this want of paths of communication, and the lack of harmony of development in the different nervous elements, render the organ imperfect. In the central nervous system everything depends not on the quantity but on the quality of the elements, and their combinations with each other. The richness of the layer of neuroblasts in the hemispheres of idiots, which indicates true arrest of development of certain parts of the cerebral tissue, undoubtedly produces insufficiency of function of the nervous system and of the manifestations of the intellect. In favourable conditions of nutrition, however, neuroblasts may become transformed into elements of a superior order, that is to say, nerve cells. In the layer of neuroblasts there are sometimes found polymorphic cells. Thus the neuroblasts, which for a certain time preserve their embryonic forms, and which are in a state of functional lethargy, may under the influence of a propitious impulse become transformed into nerve cells and help in reinforcing the activity of the cerebral functions. It is perhaps in this way that are to be explained the cases of profound and apparently hopeless idiocy in which there sometimes in a manner not at present understood occurs a marked improvement of the intellectual faculties. The idiot seems to awake from a long sleep whilst nevertheless retaining permanently the stamp of his mental infirmity, though in a less marked degree.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF PHARMACOLOGY, THERAPEUTICS, AND MATERIA MEDICA.

(123) Treatment of Biliary Lithiasis.

IN introducing this subject Professor NAUNYN (Strassburg) said: The formation of biliary calculi does not take place solely in the gall bladder. Some are formed in the ramifications of the hepatic duct. Cholesterine and calcium (bilirubinate of lime), the chief chemical constituents of biliary calculi, come from the mucous membrane of the biliary ducts. Lithogenic catarrhs of the mucous membrane may be excited by microbes (coli bacillus, Eberth's bacillus, possibly also by others). They are therefore of infectious origin. Nevertheless, great virulence of the germs is by no means favourable to the formation of concretions. It is rather slight infections caused by microbes whose virulence has been attenuated that induce lithogenic catarrhs. These slight infections may become developed as soon as there is stagnation of bile. Indeed, normal bile is not absolutely sterile, but the germs, among which only the coli bacillus need be mentioned, are present in very limited number, and have no virulent property as long as evacuation of the bile proceeds in a normal manner. From what has been said it may be gathered that in ultimate analysis it is disturbances in the flow and evacuation of the bile that are the principal causes of the formation of biliary concretions. The space of time required for the formation of the different kinds of biliary calculi is of very variable length. It is not impossible that the formation of one or other kind of calculus may take place very rapidly. Biliary concretions may remain for a long time in the gall bladder without their presence being indicated by any symptom. Among the evil results caused by the presence of calculi in the bile passages, inflammations of mucous membrane, cholecystitis and calculous cholangitis occupy the foremost place. They are of infectious origin, and may be induced by the appearance in the bile of microbes proceeding from the blood (Eberth's bacillus) or from the intestine. If any calculi are present, there these microbes multiply with great rapidity. In fact, the calculi prevent evacuation of the bile, and just like the residual urine in the bladder, the residual bile, that is to say, the permanent residue of bile, forms an excellent soil for the development of an infection. The residual bile may in like manner be the starting-point of auto-infections of grave character. The coli bacillus which is almost invariably present in normal bile may become extremely virulent in residual bile. This infectious cholecystitis may cause an expulsion of calculi, and in this manner become the starting-point of hepatic colic and icterus. On the other hand, hepatic colic may become the starting-point of a cholecystitis when a calculus owing to other causes escapes from the gall bladder. Cholelithiasis may be cured in each phase of its evolution by evacuation of all the calculi. This evacuation may take place by the natural channels as well as through the formation of fistulæ. In the great majority of so-called "cures" one has to do only with a cure of the infectious complications. The disease becomes latent as soon as the bile ducts are no longer obstructed. It is impossible to foretell the duration of such a state of apparent cure; it may be indefinite. The surgeon alone can place before him complete cure as an object to be aimed at. Nevertheless, a complete cure is not altogether the same thing as the evacuation of calculi by operation. There are cases in which pain and the appearance of calculi in the stools persist after operation. As for internal medication, it can aspire only to remove obstruction of the bile passages and to remedy the infectious complications. Once the disease has become latent, the object of medical treatment is attained. The most efficacious means is the most abundant possible secretion of bile. It is, however, more than doubtful whether the remedies that cause an abundant secretion of bile under normal conditions produce the same effect when the bile channels are obstructed (infectious cholangitis). The inefficacy of ordinary cholagogues as long as an infectious cholangitis exists seems only natural. As regards medical therapeutics, it is only apparent cure that can be aimed at by its means, and to obtain this the practitioner must place before himself two objects: (1) To mobilise the calculi contained in the bile duct, the cystic duct, or the gall bladder, and to modify the concomitant infectious alteration of the bile passages. The method of fulfilling the former indication has given rise to much discussion, for the muscular coat of the excretory channels, the contraction of which contributes very effectually to the expulsion of concretions, may also by spasm imprison them, so that one has to choose between excitants (purgatives, emetics, cold wraps, and electricity) intended to increase contraction, and sedatives (opiates, belladonna, chloroform, and hot water internally and externally) intended to bring about relaxation of the spasm. Dr. Naunyn thinks that unquestionably the latter procedure is the more logical, and it is to it that he has recourse. He summed up his view on this matter in the formula: No emetics or purgatives, but opium and heat. With regard to cholagogues, theoretically the production of a larger quantity of bile seems as if it ought to favour the expulsion of the calculus; in reality, however, it is not the volume of the bile that is important, but its pressure in the biliary ducts, and if one takes into consideration the fact that according to Heidenhain that pressure does not exceed 300 mm. of water, whilst Oggi has shown that the sphincter of the bile duct only allows itself to be forced by a pressure of 700 mm. of water, it will be understood that the action of cholagogues is very feeble, if there be any at all. Olive oil and oleate of sodium, which have recently been employed successfully by many practitioners, but of which Dr. Naunyn has had no personal experience, undoubtedly act directly on the mucous membrane in question. The same thing possibly holds good with regard to hot sulphate of soda waters. As regards alkaline waters, the efficaciousness of which has for so long been an article of faith, it appears to Dr. Naunyn beyond question that they do not exert any kind of solvent action on calculi. As regards the cholagogue effect, it has never been clearly demonstrated, and, moreover, Dr. Naunyn does not think that if they had such an effect it would be of any use. Must it therefore, he asks, be admitted that hot mineral water has a sedative effect on the nervous phenomena which cause occlusion of the sphincter of the bile duct? This is possible, but the fact that alkaline waters also act upon affections of the liver quite different from cholelithiasis leads him to attribute to them a special action on the circulation of the liver, which, under their influence, becomes particularly active, and brings to the tissue a more abundant and richer blood, thus making possible an easier repair of pre-existent lesions.

MM. A. GILBERT AND L. FOURNIER (Paris) dealt with the subject under five heads: (1) *Nature of Biliary Lithiasis.*—Biliary lithiasis is in the generality of cases the result of a microbic action—and most commonly of a coli-bacillary action—on the mucous membrane of the channels for the excretion of the bile (intrahepatic and extrahepatic ducts, gall bladder). Ascending infection by germs feebly but sufficiently virulent determines a catarrhal angio-cholecystitis. The mucus abundantly secreted and the desquamated and degenerated epithelium furnish in large quantity the lime and cholesterin which are the principal constituent elements of calculi. The lime combines with pigments to form insoluble compounds. The small precipitates (bilirubinate of lime), and the desquamated epithelial cells agglutinated by mucus, may form the primary centres, the nuclei of the calculi. Biliary lithiasis therefore constitutes the type of lithiasis of parietal origin as contrasted with lithiasis of secretory origin. Ascending infection of the bile ducts takes place with extreme frequency under very various influences. Biliary stasis is its essential condition. This acts also by retaining within the excretory channels the calculi that are recent formation, small in size, and soft, and by permitting their growth

and increase of consistence. It is not impossible that certain hetero-intoxications or auto-intoxications are lithogenic in consequence of the same process of catarrhal angiocholecystitis. (2) *Spontaneous Cures and Pseudo-Cures.*—We may conceive the possibility of a spontaneous cure of biliary lithiasis by the expulsion of calculi already formed and the *restitutio ad integrum* of the mucous membrane of the bile passages. Doubtless the same thing occurs in many circumstances, particularly in the case of recent lithiases. These are abortive lithiases in which the lithiasic product is expelled before term, that is to say, before its complete maturation. The return to the normal state of the biliary evacuation is on the other hand the essential condition of the cure of superficial biliary infections. Calculi may be expelled through fistulæ. Choledochoduodenal fistulæ are the most favourable. The atrophy and shrivelling of the gall bladder over calculi, and the encapsulation of the latter, constitute only pseudo-cures which by no means protect the patients against the occurrence of serious complications. (3) *Prophylaxis.*—Certain hygienic rules constitute in themselves true prophylactic means against lithiasis (regular meals, taken at short intervals, the use of clothing which does not cause displacement or deformation of the abdominal organs, exercise, etc., careful regulation of the digestive functions); one of their principal results is indeed to prevent to a certain degree stasis of the bile and ascending infection. The prophylactic treatment should be complemented in all cases where the conditions that are the habitual causes of lithiasis are present by a series of therapeutic measures (use of alkaline substances, cholagogues, massage of the abdomen, and, in particular, of the gall bladder, large cold enemata), particularly after pregnancy and after general diseases that are frequently accompanied by ascending biliary infections (typhoid fever, malaria). (4) *Treatment of Lithiasis when Developed.*—The same hygienic rules are applicable to the treatment of lithiasis when developed. What is known of the action of the different cholagogues and lithontriptic substances does not at present warrant the hope of obtaining a cure of biliary lithiasis by means of them. Nevertheless, it is evident that the expulsion of numerous calculi and considerable improvement, if not true cure, are obtained by regular courses of treatment in certain mineral water stations. On the other hand, the authors believe that the question of lithontriptics is not yet definitively settled, and that researches having for their object the breaking up and destruction of calculi within the biliary passages deserve to be carried further. Such a result if it were obtained, though not directly attacking the cause but only the effect, would be all the more valuable, as the danger run by a subject of lithiasis is caused in great measure by the calculi. The presence of these in the biliary passages, their normal and especially their abnormal movements are, in fact, the most potent causes of secondary infections, which are sometimes of great gravity, and of profound changes not only of the biliary passages, but also of the liver itself. (5) *Indications for Surgical Intervention.*—The threatening of serious complications is the essential indication for surgical intervention. The signs of a chronic obstruction of the bile duct, swelling, signs of intrahepatic angiocholitis, the occurrence of painful crises too frequently repeated, especially if they are accompanied by febrile phenomena, are the principal circumstances in which surgical intervention has to be considered. The recent progress of the surgery of the bile passages has rendered the prognosis of complicated lithiases much less unfavourable than it was.

DR. EHRETT (Strassburg), said that, in conjunction with Dr. Stolz he had made numerous experiments with the object of ascertaining the amount of micro-organisms present in the bile as well as the conditions favouring pullulation of the germs in the biliary ducts. They first satisfied themselves that in the normal state the bile, though only feebly antiseptic, is none the less almost sterile. In fact, cultures are obtained from it only by sowing large quantities of biliary fluid (4 to 5 c.cm. at least); even in those conditions scarcely 10 colonies per cubic centimetre of bile sown are obtained, and, moreover, the germs are of very attenuated virulence. After injection of a culture of streptococcus into the gall bladder the bile ducts clear themselves very rapidly of the microbes thus introduced, and after eight days the bile is as aseptic as it is in the normal state. Absolutely analogous results are obtained when infection is produced through the blood. The streptococci disappear as quickly from the bile as from the blood, and the return of the bile ducts to the normal state is accomplished in about a fortnight. On the other hand, if there are introduced into the gall bladder foreign bodies perfectly aseptic but capable of interfering with the contractility of that receptacle, the bile becoming stagnant is rapidly invaded by innumerable micro-organisms among which the coli bacillus predominates. There is no doubt that this pullulation of microbes is due to the forced immobility of the gall bladder and to the presence of residual bile. These facts appear to Dr. Ehrett to establish the importance of the evacuation of the bile for the integrity of the excretory ducts of the liver, and they account for the frequency of infection of the bile ducts in all circumstances in which their permeability is compromised by the presence of calculi.

DR. DOYEN said: Surgical intervention in biliary infection is sometimes urgent, and in regard to certain cases there can be no discussion about this. It is clear that a gall bladder full of pus must be emptied on the same principles as any other purulent infection. Apart from those indications, there are certain contingencies which may bring the lithiasic patient within the province of the surgeon. Whenever there exist signs of chronic obstruction of the bile duct, one should operate within a period of five to six weeks in order to prevent the development of a cirrhosis which, by the disturbance of the general health entailed by it, would constitute an absolute contraindication. From the point of view of technique, everything depends on the condition of the gall bladder, which may be free or adherent. In the former case the surgeon may confine himself to simple evacuation of the gall bladder and removal of calculi. Nevertheless, M. Doyen has a leaning to cholecystectomy since he has succeeded in performing that operation by the subperitoneal route, which prevents all danger of the overflow of bile into the abdomen. On the other hand, when the gall bladder is adherent, the adhesions must, if possible, be torn through with the finger. Sometimes, however, the gall bladder is retracted on the under surface of the liver, and buried in the thickness of an enormous mass of inflammatory adhesions. When this condition is present he does not hesitate to perform transhepatic puncture of the gall bladder. Anastomosis of the gall bladder with the duodenum appears to M. Doyen to be indicated only in the very rare cases where there is cicatricial obstruction of the bile duct or the ampulla of Vater.

---

(133) Indications for Bleeding.

PROFESSOR GEORGES HAYEM (Paris), introduced a discussion on this subject. He summed up his conclusions as follows: (1) A therapeutic measure is *indicated* when it is established that in certain given circumstances it gives greater relief than any other. Bleeding, therefore, can be looked upon as *indicated* only in the cases in which it acts in a manner unquestionably superior to all other therapeutic measures. (2) The employment of repeated bleedings as a method of treatment, formerly called the antiphlogistic method, appears to be definitively condemned. On the other hand, the opening of a vein once or several times at relatively long intervals deserves to be preserved as a useful and sometimes heroic measure. (3) The cases in which bleeding is indicated are, generally speaking, those in which life is placed in immediate danger either by disturbances of the circulation or by toxæmia. (4) The principal conditions in which bleeding is clearly indicated are the following: acute œdema of the lung, particularly in diseases of the large vessels and the kidneys; certain cases of pneumonia of œdematous or simply congestive form; certain mechanical disturbances of the circulation due to disease of the heart or the great vessels, particularly in the case of arterial hypertension, but also sometimes with evident asystoly; congestive and hæmorrhagic forms of acute nephritis; cerebral congestion and

hæmorrhage at the beginning in patients who are the subjects of hypertension; acute or recent uræmia, puerperal eclampsia; poisoning of the blood by certain gases, notably by carbonic oxide. (5) In all other pathological conditions the indications for bleeding are disputable; this is notably the case as regards chlorosis. (6) The indications for bleeding are established empirically by observation. In this respect records of any real value are very few. Statistics are scarcely utilisable, for it is very difficult to group facts which are often of disparate character in a satisfactory manner. The so-called physiological effects of withdrawal of blood can give only a very imperfect idea of the therapeutic effects of bleeding. These result essentially from the peculiar conditions created by the disease. It appears to be possible to connect them in large measure on the one hand with the mechanical effect produced by sudden withdrawal of a certain quantity of blood, on the other with an elimination of toxic material. Clinical facts observed with accuracy prove that these therapeutic effects are very powerful. (8) The resistance of man and the higher animals to withdrawal of blood is considerable, in all cases where there does not exist a pathological cause of deglobulinisation or an obstacle to the renewal of the blood. Except at the extreme ends of life, in the morbid conditions that have been mentioned a fairly considerable bleeding (300 to 500 c.cm.) is always easily borne, even when the patients are markedly anæmic, which happens with considerable frequency in uræmia and puerperal eclampsia. (9) The renewal of the blood takes place in sick people, as in the physiological state, by the intermediary of the hæmatoblasts; the elements of the marrow of bones take no part in it. These elements pass into the general circulation only in cases of excessive loss of blood repeated time after time.

M. A. Robin said that, in addition to the mechanical and antitoxic effects of bleeding, a considerable share must be attributed to the action which the withdrawal of blood had on nutrition and organic exchanges. These effects, which hitherto have been little known, are constant and considerable, and seem to M. Robin to throw light on the mode of action of bleeding. Researches carried out by him for many years have satisfied him that, after bleeding to 150 to 250 grams in patients suffering from pneumonia, uræmia, and heart disease, the occurrence of polyuria is regularly observed, whilst at the same time the standard of solid materials—urea, phosphoric acid, nitrogen—is notably increased. On the other hand, pulmonary ventilation is accelerated; in one case the amount of air traversing the lung was increased by 61 per cent. The proportion of oxygen consumed by the tissues undergoes a parallel augmentation. Analogous but less considerable changes are observed after hæmorrhage, either physiological (menstruation) or pathological (epistaxis, hæmatemesis from simple ulcer of stomach). M. Robin summed up his view in the statement that bleeding is an excellent means of increasing cellular oxidation. He held that it is therefore indicated in all cases where nutrition is compromised not by excess of disassimilation but by insufficiency of oxidation.

(134) Should Fever be Treated?

Dr. Stokvis (of Amsterdam) said there are certain cases, though they are rare, in which it is impossible not to intervene in a case of fever. As, when alarming symptoms connected with the great functions of the economy (heart, respiratory apparatus, nervous system) place the patient in imminent danger of collapse. In such circumstances inactivity is out of place. But how is the practitioner to interfere? Dr. Stokvis thinks it is a serious error to try to reduce the temperature by the administration of antipyretics, and holds that recourse should be had solely to hydrotherapy and to the use of analeptics. The employment of medicinal agents, however, is sometimes legitimate in the absence of any threatening collapse. This applies to affections for which we have a specific medication, for in that case it is not only the pyrexia that we can combat but the fever itself. Unhappily this is very seldom the case, and, except in regard to malaria and acute articular rheumatism, the specific antipyretic is still to seek. In presence of a febrile malady it is equally exceptional to have to deal with symptoms of immediate gravity and to be in possession of a specific medication. Dr. Stokvis is, therefore, of opinion that the general rule, which applies to the immense majority of cases, is not to treat persons suffering from fever but to nurse them. He thinks that it is not by drugs but by hygiene and diet that one should deal with such cases.

Professor Lépine (Lyons) said that from antiquity up to the present century the healing virtue of fever had been held as a kind of dogma. Liebermeister taught that the heat was the enemy to be fought. The treatment of pyrexia is the treatment of fever. More attentive observation, however, has shown that if pyrexia generally speaking indicates the gravity of a febrile malady, it is far from being the principal factor of it, and an endeavour must be made to treat the fevers specifically. This fortunate result has been reached as regards certain diseases, but as regards others the practitioner is reduced to watching the reaction of the organism, sometimes by moderating it by means of antipyretics which are to a slight extent specific in regard to certain pyrexiæ; sometimes by stimulating it by hydrotherapeutic measures; sometimes by the application of cold (especially in the case of hyperpyrexia); lastly by supporting the system.

M. A. Robin maintained that the treatment of fever should be based on a study of the organic exchanges in the pyrexial patient. From this point of view two types of pyrexia must be distinguished: a simple pyrexia in which the general oxidations and the respiratory activity are increased; and a grave pyrexia produced by profound infections, the effect of which is to diminish oxidations, and on the other hand to increase disassimilation. Antipyretics, which are the moderators of oxidation, are therefore indicated in fever of the former type, while they can only be hurtful in the the latter. In dealing with this grave form of pyrexia the aim of the therapeutist should be threefold: 1. He should endeavour to diminish the phenomena of disintegration. For this purpose certain antipyretics, such as sulphate of quinine, may be very useful, provided they are given in small doses (50 to 60 centigrams to be taken in three doses in 24 hours), for the ordinary doses would produce the opposite effect. The analeptic treatment treatment recommended by Dr. Stokvis fulfils the same indication. 2. He must promote oxidation by aëration, by inhalation of oxygen, by the drinking of large quantities of fluid, and especially by hydrotherapy. 3. He must combat the retention of organic residues and facilitate their elimination, and to this end making them soluble. Oxidation itself is a very general process of solubilisation. Further, by the administration of salicylic and benzoic acid the insoluble glycocol is transformed into salicyluric or hippuric acid, which are easily eliminated by the urine. In short, M. Robin holds that there are fevers that must be respected and fevers that must be combated; and for this latter purpose it is not sufficient to fight the pyrexia, which is only an outward expression of the febrile state.

M. Huchard said the question did not admit of only one solution. Illustrating by a few examples the diversity of indications furnished by one and the same pyrexia, he said it is easy to assure oneself that the mere symptom pyrexia does not give an idea of the gravity of the febrile state. Whilst a temperature of 40° or 40.5° is normal in scarlatina, it becomes alarming in acute articular rheumatism. In typhoid fever again, as everyone knows, acceleration of the pulse is a more disquieting sign than increase of temperature. Again in pneumonia diminution in the amount of chlorides in the urine, if it falls below 50 centigrams in twenty-four hours, indicates a very grave, if not fatal, condition. In pulmonary tuberculosis (in the treatment of which quinine has been so much abused) it would not be rational always to use the same antipyretic, seeing that the fever is the result of at least three different mechanisms (fever of germination, fever of inflammation, fever of absorption). In like manner the "Pfeifferian fever," in pure influenza, and the pyrexia dependent upon associated affections, should not be treated in the same manner. In dealing with a case of fever two different results may be obtained—*antithermia*, easy to produce but of little

utility; and *antipyresis*, much more difficult to produce, for an antipyretic should at the same time quicken organic *chimisme*, increase diuresis, and give tone to the nervous system. This threefold end may sometimes be attained by combining the use of quinine in small doses with that of cold baths.

(135) Physiological and Therapeutic Actions of Digitalis and of its Active Principles.

Sir Lauder Brunton presented a communication on this subject in which he summarised his conclusions as follows: (1) The physiological action of digitalis is exerted chiefly (*a*) on the heart, (*b*) on the blood vessels, (*c*) on the secretion of urine. (2) Its action on the heart is that it (*a*) slows the cardiac beats chiefly by stimulation of the roots of the vagus in mammals, (*b*) increases the force of systole, and (*c*) increases the extent of expansion in diastole. Both *b* and *c* are due to an action on the cardiac muscle. (3) It contracts the peripheral vessels, and thus slows the current of blood through them. (4) By its combined action of contracting the peripheral vessels and of increasing the power of the heart it raises the blood pressure. (5) The diuresis which digitalis produces is chiefly due to increase of blood pressure. (6) Digitalis contracts the arterioles in the kidney sooner than those in other parts of the body. The renal vessels may contract so much as to arrest the secretion of urine altogether, although the general blood pressure is high. (7) When blood pressure is already high, digitalis cannot be expected to have a powerful diuretic action; but if the blood pressure be low, from natural constitution or disease, digitalis will have a diuretic action. (8) Digitalis is a local anæsthetic, but also produces pain. It therefore belongs to the class termed by Liebreich "anæsthetica dolorosa." (9) In large or in accumulated doses it gives rise to gastric irritation. (10) The action of digitalis is due to digitalin, digitaleine, and digitoxin. These principles all have an action similar in kind but differing in degree. (11) The therapeutic actions of digitalis and of its active principles are that they (*a*) regulate the heart's action, (*b*) assist a failing circulation, and (*c*) act as diuretics. (12) The regulating action of digitalis is useful in palpitation and functional disturbances of rhythm. (13) The most important use of digitalis and of its active principles is in the treatment of mitral incompetence due either to disease of the valves or dilatation of the ventricle. (14) In cases of aortic regurgitation digitalis is (*a*) unnecessary and not without danger when compensation is complete, (*b*) very useful when compensation fails. (15) When the blood pressure is already high digitalis may be injurious by increasing it still farther, and thus causing symptoms of angina pectoris or tending to produce apoplexy.

Dr. Joanin (Paris) said that of all medicinal substances of vegetable origin there are few which have raised scientific controversies so protracted and so numerous as digitalis. The fundamental remedial properties of this plant were recognised almost at once. Although since its introduction some twenty-five years ago, it has been proposed to use digitalis in the treatment of various affections, the plant has always been considered as the medicament of choice in the treatment of certain pathological conditions of the cardio-vascular system. Its use in the latter class of cases is nowadays very precisely defined, and clinical observation has accurately determined its advantages and benefits. But if the clinician is well informed from the didactic point of view as to the good effects which he has a right to look for from the administration of digitalis, the case is by no means the same when from the practical point of view he seeks to give the patient the benefit of the advantages which theory has taught him to anticipate. The results of the treatment are inconstant, and in this regard practice is not in agreement with theory. The author has sought to find answers to the following two questions: On what depends the inconstancy of the effects, and how can it be remedied? In the great majority of cases failure results either (1) from the employment of defective preparations, the defect being due to the extreme variability in composition of the substance dependent on the place and time of the gathering of the plant, the drying of it, and its possible adulterations; (2) from the employment of products bearing a great diversity of names, which pass for the immediate active principles of the plant, and are obtained industrially by very different methods; (3) from the use of the same name in certain cases to designate different substances on the market. The only way to avoid the errors and inconstancies of action attributable to the preparations used appears to Dr. Joanin to be the unification of the means of control and the methods adopted for obtaining the different products. In view of the variability of composition of the different organs of the plant, and of the multiplicity of the factors which are the causes of these variations, it might be well (*a*) to attempt to establish a control (by analytical procedure and physiological experiment) on digitalis leaves in the market, so as to place in the hands of the pharmacist a product as to which he would be fully informed, and the genuineness of which he might verify for himself; (*b*) to adopt a rigorous method of procedure for the obtaining of a galenical preparation, conserving as far as possible the physiological properties recognised as belonging to the plant, and to submit the galenical preparations thus obtained to the same control as the plant itself. As far as the active principles are concerned, Dr. Joanin suggests that it would be advantageous (*a*) to adopt a uniform terminology for the designation of the same substances; (*b*) to establish with precision the method of obtaining the different immediate principles which seem to be chemically defined; (*c*) to adopt a uniform method for the extraction of these active principles.

(136) Treatment of Arrests of Development.

Dr. Springer, of Paris, said the various influences, whether hereditary (syphilis, alcohol), or acquired (infections, intoxications), which determine arrests of development, in ultimate analysis, act on the connective cartilages, particularly on that of the lower end of the femur. Electrical stimulation of these organs is capable of quickening their functional activity, and bringing about a renewal of the process of growth. In order, however, that this method should give the best results, it is necessary to place the organism in the best possible conditions of nutrition. This is accomplished by previously treating any coexisting pathological conditions, notably gastro-intestinal and hepatic disorders. It is well to associate with the electrical treatment the administration of preparations of thyroid, since insufficiency of the thyroid body is frequent in the subjects of incomplete development. For the purpose of avoiding the bad effect on the nutrition which these preparations often produce, Dr. Springer recommends the use of a fresh decoction of barley or other cereal substance as a habitual drink. By this combination of therapeutic methods he has succeeded in bringing about a growth of several centimetres in a few weeks, and this even in persons who have passed the age when it is generally believed that growth is ended (25 years in one case, 32 in another).

(137) Ergotin in Pneumonia.

Dr. Kleczkowski (Grand-Fresnoy) said that ergotin employed in a daily dose of 3 to 5 grams from the period of rigor, before the appearance of bronchial breathing, had the effect of making the disease go through its evolution in four or five days. Given later it does not appreciably shorten the duration of the febrile stage; but it moderates the fever, relieves the dyspnœa, and calms the delirium, which never resists its action more than twenty-four hours. Dr. Kleczkowski has used this treatment for eighteen years, and in all that period has never seen a single fatal case of pneumonia except in diabetic subjects.

(138) Sodium Sulphate in Small Doses as a Laxative.

Dr. Manquat (Nice) said a small dose of sodium sulphate (4 to 8 grams) dissolved in a large glass of water at 38° C. taken in the morning fasting is a laxative which can be recommended for ordinary constipation, and also in patients in whom it is important to prevent any effort in emptying the bowel (piles, apoplexy, persons on whom abdominal operations have been performed, etc.). Moreover, by the regular use of the same solution it is possible to obtain a true mineral water "cure" which has given him the best results in a certain number of dyspeptics. In such cases the treatment should be suspended for ten days every month.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

THIRTEENTH INTERNATIONAL CONGRESS OF MEDICINE.

HELD IN PARIS, AUGUST 2nd to 9th.

SECTION OF PATHOLOGY.

(139) The Histogenesis of Malignant Tumours.

Professor V. Babes (Bucharest) presented a communication on the histogenesis of epithelioma, in which he said that although the origin of such tumours was one of the obscurest problems of pathology, a solid basis for attacking it might be found by bearing in mind the following principles:—(1) The notion of cancer and epithelioma should be precisely defined. At the present time, especially in France, people talk of cancers which are not epitheliomata and of epitheliomata which are not cancerous. From the histogenetic point of view, one must regard as cancers only new growths of epithelial origin possessing malignant characters not only in point of site, but especially as regard their intimate relation with the lymphatic system, by which path are produced metastases and relapses, and a special cachexia is determined. (2) This limitation is necessary on the one hand because of the relations of epitheliomata to surfaces and to surrounding tissues; and, on the other hand, in order that it may be possible to apply a natural classification to those tumours. (3) From the careful study of a large series of cancers, the impression is obtained that in most of these cases the new growth begins by non-cancerous lesions which at a certain time, changing their characters, become cancerous. It must be admitted that congenital tumours or epithelial germs misplaced or detached from their natural continuity at a more or less advanced stage of development constitute in a large number of cases the soil on which cancer develops; and the departure from the fundamental rules of development becomes more and more pronounced. A similar departure will occur if the adult epithelium becomes the seat of a chronic irritation by displacing it, changing its relation to neighbouring tissues, and forcing it to develop in the substance in an independent manner. The same displacement will take place if by weakening of the tissues at an advanced age the epithelium in certain regions is placed in special conditions of liability to proliferation. (4) The architecture and finer structure of cancers is fairly well known, and it may easily be ascertained with the microscope at what moment a chronic inflammation, a tuberculous, or a benign epithelial tumour changes its character and becomes cancerous. (5) The vital question in regard to the histogenesis of cancer is to know whether the departure from the rules of development and normal growth may begin from the operation of causes inherent in the soil, or whether some casual determining cause must be invoked for that effect. Again, there is the further question whether such a cause must be specific in character or whether it also may be ordinary. (6) It is undoubted that cancer declares itself at the time when the epithelium of the integuments or of the glands shows a tendency to emancipate itself to enter on a career of irregular proliferation, to become detached and form substantive colonies, leaving the basal membrane and entering first into the lymph spaces in the form of plugs or solid cords. In such modified conditions of life the epithelium necessarily changes character, forming irregular mitoses, abnormal secretions, and special degenerations. Having no longer normal outlets or relation with the surfaces, all the special products of epithelium remain enclosed in the heart of the colonies or the cells. (7) A series of careful workers using excellent methods for the demonstration of the products of this irregular working of cancer colonies have shewn that the cellular intrusions which have been taken for parasites of cancer are only very varied modifications of the nucleus, nucleoli, nuclein, and paranuclein of substances engaged in the process of karyokinesis, the protoplasm inclusions of other cells, leucocytes, or epithelial cells, atrophies, and degenerations—keratinic, hyaline, filamentous, mucous or pseudo-mucous vitreous, colloid, amyloid, hydropic, etc. (8) As most of the most curious formations which have been looked upon as parasites have been recognised to be products of cellular transformations, there is no justification for regarding as parasites certain formations whose origin has not yet been fully elucidated. In fact, the morphological characters and histo chemical reactions of the different phases of developments of coccidia or blastomycetes differs essentially from the inclusions of carcinoma. (9) All serious authors recognise that the parasitic neoplasms produced by coccidia and by blastomycetes differ essentially from true cancer, coccidial tumours having a papillomatous structure and those produced in animals by blastomycetes having the characters of a chronic inflammation, with or without participation of epithelium. (10) The communicable tumours of certain animals have likewise a structure differing from cancer, being papillomatous or adenomatous. In their genesis a large part must be attributed to local or family proclivity. (11) If researches on the nature and parasitic origin of cancer have up to the present failed, the question presents itself whether the idea of the parasitism and specificity of cancer should be given up. Babes holds that, on the contrary, it should be taken up again and the investigation pursued along other lines to reach a certain conclusion. With this end in view new methods should be sought for the demonstration of parasites or specific substances in cancer, those made up to the present in that direction not being conclusive. The question must be carefully studied whether, as a matter of fact, cancer gives rise to epidemics and endemics analogous to those of infectious diseases, and the search for an effective method of transplantation of cancerous tissue must not be abandoned. (12) But histogenetic researches tending to prove the non-specificity of cancer should not be neglected, as these have hitherto given encouraging results. Since one is forced to admit that the majority of tumours, and especially of epitheliomata, have their origin in anomalies, displacements, irregularities in the development of tissues, what ground is there *a priori* for the exclusion of carcinoma from the category of such tumours? The question of site, which has been rather neglected recently under the influence of the great bacteriological discoveries, is gradually regaining its place in the interpretation of diseases; and we must ask whether special peculiarities in the site of disease cannot impress on these characters analogous to those of specificity. As Babes has shown that non-specific microbes can produce true epidemics among the patients of a hospital ordinary irritant causes, traumatisms, tuberculosis, or leprosy, or other chronic irritations may possibly determine in a soil prepared by anomalies or by epithelial tumours the vicious growth and peculiar degenerations of cancer. (13) As cancer essentially corresponds to a microscopic picture characterised by profound derangement in the architecture and in the direction of proliferation of epithelium, it may be assumed that any kind of irritation, mechanical, chemical, or infectious, acting on the predisposed epithelial tissue—that is, a tissue liable to enter on irregular and profound proliferation may determine the derangement which the clinical course of the disease inevitably entails. (14) There is no objection to the supposition that whatever may be the intimate nature of the deep irritation of a certain predisposed region of the body, or of a wart, a papilloma, an adenoma, a chronic ulcer, or a tuberculous lesion, as soon as epithelium becomes deranged downwards in a certain manner, there results therefrom always the same tissue, with similar disastrous consequences for the organism. Babes's personal researches on cancers developed on the site of a chronic tuberculosis, on carcinoma of the cirrhotic liver, on cancer of the tongue developed in a patch of leucoplasia, plead rather in favour of this view.

Professor W. Podwyssotzki (Kieff) dealt with phagocytosis and autophagism in cancers and other tumours. He said (1) the process of phagocytosis is widespread among malignant tumours, and is a means of defence, though an imperfect one, on the part of the mesoderm against the progressive encroachment of the neoplastic tissue. This process has been

observed by Klebs, Stroebe, Claessen, Korotneff, Soudakevitch, Ruffer, and others, but the interpretation of it has often been wrong. (2) This process of defence is exercised in different tumours in a very different manner, although it is always the cells of mesodermic origin that work at the destruction of a certain number of the cells of the tumour itself. There is also a great difference in the degree of resistance of the cells of different tumours in regard to this destructive and phagocytic action of the mesoderm, although cancers of epithelial origin produce in the surrounding connective tissue a more or less powerful inflammatory reaction which might be regarded as an attempt at defence on the part of the mesoderm against the invasion of the epithelial tumour. The cancerous cells themselves, however, appear to be less amenable to the phagocytic and histolytic action of the mesoderm; as long as the epithelial cancerous cell is young and full of life it can defy the phagocytes. It is only cells in course of regressive metamorphosis and cells already dead that succumb to the invasion of the phagocytes, and as such epithelial cells are only found in the interior of cancer buds at a distance from vessels, it is evident that it is only the mobile phagocytes—the leucocytes—that work at the definitive destruction of these cancerous cells. In this case the leucocytes are true necrophages. Around the weakened cells there is observed an agglomeration of polynuclear leucocytes which devour them, with the help of an intracellular, but more often extracellular, phagocytosis. This process is most evident in cancroid tumours. (3) Between a living cell and one in course of degeneration or already dead there is this main bacteriological difference—that the living cell should produce some kind of defensive substance against the mesoderm and against the invasion of leucocytes, and that this substance is completely wanting in cells that are dead or in course of degeneration. On the other hand, the latter produce a substance having a very pronounced positive chemiotaxis, and it is evidently to this substance that are due the the attraction and invasion of the leucocytes from the vessels towards the degenerative or dead cancerous cells. (4) The inflammatory reaction produced in the connective tissue by the growth of the cancer buds, although accompanied by a whole army of mesodermic elements possessing great histolytic and phagocytic power, in no way contributes to the destruction of the epithelial cells. The principal cause of this relative weakness of the mesoderm in regard to the cancerous cells is the defensive substance with which cancerous cells, when young and in a state of proliferation, are normally endowed. On the other hand, the reaction on the part of the connective tissue, followed by its growth in the direction of the cancer buds, contributes to a disorientation of the epithelial cells, as has been shown by Kibbert and Fabre-Domergue, and causes an acceleration in the growth of the cancer. The leucocytes alone, as being mobile mesodermic elements capable of introducing themselves into the interior of the epithelial buds take part in the destruction of the weakened epithelial cells. But as these cells are already in course of degeneration this phagocytic work represents only a necrophagism, and for that reason hardly counts in the defence of the mesoderm against the tumour. (5) In a whole series of round-celled sarcomata, and in some endothelial cancers, a very pronounced phagocytosis is often met with. The phagocytic action is produced sometimes by the cells forming the principal mass of the tumour, sometimes by special cells larger than the cells of the tumour itself. These large cells represent true macrophages and are provided with a large oval nucleus; sometimes they are giant cells. The protoplasm of these macrophages contains sometimes a single cellular inclusion, sometimes a mass of such. Part of Virchow's physaliphores and of the so-called parasitic inclusions are nothing more than a phagocytosis with vacuolisation around the englobed cell. In a series of microscopic plates may be studied all the successive changes even to complete disappearance undergone by those inclusions in the interior of the macrophages. Some of the cells of the tumour phagocytosed by other cells of the same tumour—the weaker by the less weak—seem to be engulfed while still alive, as may be observed after staining of the nucleus, so that there is not only a process of necrophagism, but also one of biophagism. (6) Phagocytosis in the cases referred to being effected by the cells of the tumour itself, this process may naturally be termed "autophagism. Malignant tumours of mesodermic origin are met with in which autophagism is extremely pronounced. The process of autophagism is often accompanied by an agglomeration in the phagocyte of a mass of fatty granules and droplets, and after fixation in Flemming's solution these phagocytes are quickly recognised by the black staining of the fat. (7) The cells of the englobed tumour undergoing in the protoplasm of the phagocyte a series of degenerative changes may resemble inclusions of parasitic nature so closely that often it is absolutely impossible to differentiate them. In many cases the parasitic inclusions themselves owe their origin to a phagocytosis—that is to say, certain cells of the tumour engulf a quantity of parasites and destroy them. (8) A good, and perhaps the sole, means of treatment of cancers and inoperable malignant tumours would consist in a diminution by some means of the substance in the young cancerous and neoplastic cells, or an increase of the histolytic and phagocytic power of the mesoderms, macrophages, and leucocytes. These means have still to be sought for. (9) A part of the so called parasitic inclusions represents the centrosome hypertrophied with the zone of protoplasm surrounding it in a state of colloidal degeneration. The centrosome with its surrounding zone may depart from its normal state so far that it becomes foreign to the cell, and as such becomes detached from the protoplasm of the cell and exists free in a vacuole of greater or less size. If in certain cancers, and notably in cancroids, it has hitherto been impossible to find inclusions that are undoubtedly parasitic, the contrary may be affirmed in regard to endothelial cancers as well as cancers of the breast, pancreas, stomach, and other glands. A part of the numerous inclusions found in these cancers is of indubitably parasitic nature. But the resemblance of these parasites to inclusions due to the autophagism of the tumour, as well as to hypertrophied and degenerated centrosomes, may in some cases be so striking that differentiation is often almost impossible.

SECTION OF BACTERIOLOGY.

(140) Immunity.

Professor Buchner, of Munich, introduced a discussion on this subject. Dealing first with "natural resistance," he said that term appeared preferable to "natural immunity," more often used, because the word "immunity" may then be reserved exclusively for a very characteristic specific state altogether different from natural resistance. Natural resistance—setting aside cases of innate invulnerability in regard to toxins—consists principally in the microbicide power of the juices and of certain cells of the organism and in their richness in alexins. This also hold for the cases of cure of infective processes threatening the organism attacked, as far as the specific immunity recently acquired plays no part therein. In staphylococcus infections (furuncle, abscess, etc.) cure seems to be produced by an increase of natural resistance, local or general, not by a specific immunisation. A purely humoral theory of natural resistance has never been formulated unless by those who wish to oppose it. The alexins of the serum—without the cells—are sufficient only in very exceptional cases to explain the phenomena of resistance. Nevertheless it is impossible to exclude the alexins of serum altogether from investigation seeing that their existence implies a certain limitation of the theory of phagocytes. As it has been observed since 1894 that the alexins had their origin in the leucocytes, the researches on phagocytosis and those on the effects of the alexins have become more and more approximated in their final results, and there now remains only one point of difference that requires to be settled. Metchnikoff and Bordet themselves noted some years ago that the alexins of serum for the most part have their origin in leucocytes. They suppose, however, that one has not to do here with a secretion of living cells, but with an outflow of living alexins into the serum after death and after dissolution of the cells. This is the point of difference which requires to be cleared up by experiment. Laschtschenko has

found in Buchner's laboratory that by means of a series of different serums heated to 60° C. it is possible to extract the bactericidal alexins from the leucocytes of rabbits without destroying them. Here there is clearly a secretion without destruction of leucocytes; moreover, the leucocytes do not die so easily as is supposed. According to observations made by Nakanishi in Buchner's laboratory, leucocytes of different kinds of blood kept at a low temperature not only remain unchanged in form from 1 to 4 weeks, but also retain their vitality. In distilled water they die rapidly, but dissolution takes place very slowly, so that after 24 hours a large number of leucocytes have still preserved their form. The alexins, therefore, appear usually to be a secretion of living leucocytes, and to explain phagocytosis, it follows that the bacteria are already weakened by a chemical process before they are devoured. It is unquestionable that living and even virulent bacteria may be devoured by leucocytes, but it is known that microbes have phases of latent life during which the latent functions are suspended to be awakened again into existence at a suitable time. If, therefore, in consequence of external and hurtful influences the processes of nutrition and pullulation are arrested at intervals, it must not be concluded that the micro-organism is destroyed or weakened for ever. The chief argument against phagocytosis as a universal principle is the fact that within the body, in the exudates, etc., bacteria may be destroyed without the presence of leucocytes. It can never, therefore, be proved that even when phagocytosis is observed a chemical damage has not taken place before the engulfing. The microscope does not help us to a decision of the question, which, therefore, will long remain undecided. It is unquestionable that phagocytosis is not always an indispensable condition for the destruction of bacteria, and in order to judge of the principal *rôle* of the leucocytes, it must never be forgotten that there is a chemiotaxic attraction not only by living but by dead bacteria, by the proteins of the bacteria, by gluten, casein, etc. This proves that their essential character is that of resorption cells. The production and secretion of alexins appear to be in perfect accord with this fact when alexins are counted among the histolytic enzymes observed in the first place by Th. Leber—enzymes which can effect dissolution of the histogenic elements (for instance, in the softening of abscesses or on the injection of substances chemiotaxic for leucocytes, such as balsam of Peru). The same tissue dissolving effect may also be extended to pathological histogenic elements (softening of tubercle), and even to bacteria (bactericidal effect). Phagocytosis, or dissolution in the interior of leucocytes by the same histolytic enzymes, thus appears only as a special case as compared with the general fact of dissolution outside the leucocytes. Passing to specific immunity, Professor Buchner made three chief divisions: (1) Specific antitoxic immunity, (2) specific bactericidal immunity, (3) specific hæmolytic immunity. These three principal types of specific immunity are produced by preparatory treatment, in the case of (1) by means of specific toxins or non-toxic modifications; in the case of (2) by specific bacteria, living or dead; in the case of (3) by specific erythrocytes, fresh or heated to 60° C. In all these cases, there appears in the blood and serum of the animals treated a specific antagonistic body which is not destroyed by a temperature of 65° C. In case (1) it is the well-known antitoxin contained in antidiphtheria, antitetanus, etc., serum. In cases (2) and (3) the specific antagonistic body produces no immediately visible effect, but works first in combination with the normal non-specific alexins. There are no "specific bactericidal substances" or "specific hæmolytic substances." In both cases one has to do with combined effects, the bacteria and erythrocytes being predisposed to the effect of normal alexins by the action of the specific antagonistic bodies. At the same time it is of no consequence whether these alexins proceed from the same species of animal in which the antagonistic body has been produced by a specific treatment, or from another species. The predisposing effect, as is demonstrable, consists in specific hæmolytic immunity, in an attraction and combination between the antagonistic body and the specific erythrocytes, in consequence of which the latter are more easily dissolved by the normal alexins. For the specific bactericidal effect the conditions are doubtless the same. It must be taken as established that the antagonism of antitoxins towards specific toxins is based on a mutual combination. The true principle of specific immunity therefore, always and in all cases, consists in the special attraction and combination between the antagonistic body and the object of specific reaction (toxins, bacteria, erythrocytes, etc.). The riddle which has to be solved in the future is mainly the nature and origin of the antagonistic bodies and further the intimate nature of the specific combination which takes place between antitoxin and toxin, the antagonistic body and the object of reaction. Professor Buchner summed up his general conclusions as follows: "Natural resistance" and "specific immunity" differ in principle, the former being characterised by alexins, the latter by specific antagonistic substances. The alexins are destroyed at 60° C. They differ according to the animal species which produces them; they show no attraction towards the object of reaction. The antagonistic bodies are still stable at 65° C; they differ not according to the animal species that produces them, but according to the object of reaction which has been employed in the preparatory treatment, and they present a specific attraction towards the object of reaction with which they are combined. Alexins and antagonistic bodies act in the same organism at the same time, often concurrently. Natural resistance and specific immunity may combine their effects, the one reinforcing the other. The cure of typhoid fever, for instance, may be brought about by an increase of natural resistance concurring with a production of specific antagonistic bodies. The study and differentiation of all the phases of those two processes belongs to the domain of clinical medicine.

SECTION OF MEDICAL DISEASES OF CHILDREN.

(141) Artificial Feeding of Nurslings.

Professor O. Heubner of Berlin said that a method of artificial feeding of nurslings could be established scientifically only by the study of the healthy child born at full term, not by that of the deceased nursling. Just as the diet of a sick person could not be taken as a guide in regulating that of a healthy workman, so inferences could not be drawn as to the best way of feeding the normal nursling from failures or successes obtained in dyspeptic children. This, however, is what is often still done by medical practitioners, doubtless because they have most frequently to do with sick children. For this reason there is not available a sufficient mass of facts to serve for the scientific establishment of the most rational method of artificial feeding. Every year hundreds of thousands of children are successfully nourished artificially during their first twelve months of life. Nevertheless observations continued for a long time so as to give information as to the qualitative and quantitative method of artificial daily feeding of children whose growth has taken place satisfactorily are not so exact as those concerning feeding with mother's milk. For this reason we have with regard to this question more theoretical ideas than conclusive facts. At all times, however, the good sense of nurses has led them to see that nothing could better replace women's milk than animal's milk. This is confirmed by chemical analysis which shows in fact that the milk of domestic animals, especially of the cow and goat (at least as far as concerns nutritive principles) differs from woman's milk no more than the various kinds of meat differ among themselves. This is the case as regards the meat of pig and ox, which the child, like the adult, eats alternately or successively. Their general nutritive value and their potential energy are in both cases almost the same (650 to 700 calories per litre). The intestine of the healthy nursling is capable of digesting cow's milk just as well as woman's milk; only the work of digestion is greater in the former than in the latter case as the large proteid molecules require a greater digestive effort than the small hydrocarbon molecules, and cow's milk is particularly rich in the former and woman's milk in the latter. In consequence a larger amount of residue remains in the intestine after the digestion of animal milk than after that

of woman's milk. All the researches, however, hitherto made as to the organic exchanges in the nursling show that it is perfectly capable of finding the necessary amount of sustenance in cow's milk, provided it absorbs a quantity of it equivalent to that which it would get from its mother's breast at the corresponding period of development. Naturally this amount varies within certain physiological limits. The supply of artificial milk should not exceed the proper measure of the exact daily dose of animal's milk, whether diluted or not, or whether mixed with such-and-such an ingredient or otherwise. It is in the first place the drawing up of exact rules that presents the greatest difficulties in artificial feeding. Other difficulties arise from the dangers of infection and decomposition to which the animal milk finds itself exposed before its ingestion. Mother's milk is safeguarded against these dangers. We have learnt to avoid them in artificial milk feeding only since we have been brought to understand the insufficiency of macroscopic cleanliness and the necessity of asepsis. In this matter the production of sterilised milk constitutes the greatest progress of the century. To realise this condition in a satisfactory manner there is no need to heat the milk for half-an-hour at a temperature of 100°. It is sufficient to boil it for five or at most ten minutes. Even a milk heated twenty-five minutes at 65° appears to undergo perfect sterilisation without presenting changes of taste and nutritive value (Forster). It is another matter if we have to nourish artificially a dyspeptic nursling. Here the digestive power of the intestine is disturbed as well as the regular modifications of the nutritive substances. For this reason the energy gained by the elaboration of these same ingesta is weaker than in the normal condition. According to researches made in recent years it is not the protein that seems to present the greatest difficulties, as it was believed till lately, but the fat of the milk. This fact agrees with what has been demonstrated by analogous investigations made in the adult. But a too high proportion of nitrogenous material in the milk may equally become dangerous, and even the sugar, if it is not perfectly burnt up, may prove a hindrance to the good effects of the food. In such cases we must seek to attain the end by an indirect path. We must diminish the quantity of fat and of the proteid substances of the milk by diluting it to one third with boiled water, and to compensate for the diminution of energy thus brought about we must increase the quantity of sugar so as to make it correspond to that of the mother's milk (7 per cent.). One can make milk less concentrated that the natural milk richer by another hydrocarbon. For this purpose rusk is much preferable to wheat, rye, corn, or rice. Moreover an attempt may be made to facilitate the digestion of nitrogenous substances by previous artificial digestion (peptonised milk, the milk of Voltmer, Backhaus, and others in Germany). Others prefer only to lessen the quantity of proteid substances in the milk whilst endeavouring to preserve the original amount of fat by centrifugalising the diluted milk so as to obtain 1 per cent. of casein and 3 per cent. of fat (Goertner's *Fettmilch*) or by adding precisely measured quantities of cream to the diluted milk. Again, the sugar of the milk has been successfully replaced by another sugar more thoroughly burnt by the tissues of the organism, namely, maltose (Liebig's *Suppe* and Keller's *Malt-suppe*). These are the most important principles which have up to the present been most frequently applied in the preparation of artificial milks for weakly and ailing nurslings. The practitioner will succeed with one or other method, but he must feel his way. We have not yet got beyond this stage of therapeutic knowledge. If all other methods fail, one always comes back to woman's milk, which is superior to all methods of artificial feeding if we have to do with grave disease.

SECTION OF SURGERY.

(142) The Arrest of Hæmorrhage in Resection of the Liver.

DR. J. B. SEGALE, Chief Surgeon to the Duchess de Galliera Hospitals, Genoa, described what he called a new method of suture to be used in resection of the whole thickness of the liver. He said that an examination of the statistics published in recent years relative to the surgery of the liver showed an excessive number of failures, most of which were due to hæmorrhage, primary or secondary. The author believes that such failures depend partly on an imperfect operative technique, but especially on the insufficiency of the methods of hæmostasis now in use. A solution of the problem of the prevention of hæmorrhage of resection of the whole thickness of the liver can be found only in suture. He discussed the various methods of suture recommended by operators—hepatorrhaphy, which is chiefly of use in wounds; ligature, which is of service in pedunculated or pedunculable tumours; intra-hepatic ligature and interrupted suture by the methods of Kosnetzoff, Pensky, and Auvray. The author remarked that all these procedures more or less take as their *point d'appui* the hepatic and peri-hepatic tissue, which has a very feeble resistance. In practice, as operators know, what happens is that the tissue tears if the suture or ligature is pulled tight enough, while if it is not pulled tight enough it is ineffective in stopping hæmorrhage. No account is taken of the compressibility of the liver substance; thus it happens that even when the suture is effective at the time of operation, it afterwards ceases to be so, with the result that secondary hæmorrhage occurs. Dr. Segale therefore believes that the necessary conditions to make a suture sure and effective in resections of the liver are to avoid directly taking up points in the liver tissue, and to secure gradual and constant pressure. For this purpose he has devised a method after the fashion of the quilled suture, but in place of quills he uses small beads of ebony or ivory; these beads, which are hollowed in the middle, fit into each other at the ends, and are threaded together with catgut so as to form a small rod. The material was chosen because it lends itself to easy and certain disinfection, while the bead-like arrangement favours the natural encapsulation of the component parts of the rod which are incapable of absorption. The mode of use is as follows: At the boundary of the lobe of the liver which it is intended to remove, and along a transverse line, there is passed a series of loops of elastic thread of sufficient resistance for the loops to stick out on the lower surface of the liver; one of the little rods is passed through these loops by which it is held fixed, while the other is placed on the upper surface between the two free ends of the thread; these are next drawn sufficiently tight and fixed with knots of catgut. The resection is then carried out, care being taken to make the two incisions in such a fashion as to have a solution of continuity triangular in section, with the apex directed towards the middle; in this manner it is possible to bring together the free surfaces by suture. Secondary hæmorrhage is prevented by the gradual pressure which is exercised by the elastic tension of the threads; the knots when they have served their purpose soften and become absorbed; the same thing happens in the case of the catgut which threads together the beads that make up the rods, and these become broken up into small pieces which are easily encapsuled. The author gave particulars of a number of experiments on large animals, showing the harmlessness of the sutures, the perfection with which they do their work, and the complete encapsulation of the beads. Segale thinks that the experiments warrant him in affirming that the practical question which they were undertaken to solve may be regarded as settled, and that his method makes complete hæmostasis in resection of the whole thickness of the liver possible.

(143) Results Immediate and Remote of Cholecystectomy.

M. MICHAUX stated that he had performed 45 operations on the bile ducts. Among them were 32 cholecystectomies, with 4 deaths and 28 recoveries. He observed no serious complication except reflex cardiac disturbance, which occurred in 3 or 4 patients, and in 2 caused anxiety. After cholecystectomy the bile flow is generally much less abundant than after cholecystostomy; only two or three times Michaux has seen some small calculi eliminated within a few days of the operation. The results of cholecystectomy are most satisfactory both immediately after the operation and several years later. Michaux has seen all the patients operated on by him long afterwards, and was able to satisfy himself as to their perfect condition of health.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(144) Ulceration of the Stomach.

In the Section of Internal Medicine at the recent International Congress, Professor Dieulafoy presented a communication of which the following are the conclusions: There are found in the stomach ulcerations of every size, from the minute punctiform erosion up to large deep ulcers bigger than a five-franc piece. Digestive disturbances, gastric intolerance, vomiting, hæmatemesis, perforation of the stomach with its consequences, and the addition of cancer are symptoms and complications common to many ulcerations of the stomach. Instead of passing in review each of these symptoms and complications, Dieulafoy thought it preferable to choose among ulcerations of the stomach a certain number of types representing, from the clinical, pathological and anatomical point of view, sharply-defined morbid entities. As examples of some of these types he gave the following:—(1) Erosion is the smallest of ulcerations, it shows itself on the mucous membrane in the form of hæmorrhagic points more or less numerous. Notwithstanding their minute size the erosions might cause abundant hæmatemesis. (2) In certain circumstances there are found on the mucous membrane of the stomach one or more losses of substance a little more extensive than erosion. Dieulafoy has proposed for this lesion the name "exulceratio simplex." However superficial it appears, this ulceration may reach the arterioles running under the muscularis mucosæ and cause terrible hæmorrhages, often proving fatal if treatment does not prevent this consummation. (3) The simple ulcer of Cruveilhier (ulcus simplex) is the type of gastric ulcers chronic in evolution and tending to perforation. Hæmorrhage and perforation are the complications most to be dreaded. (4) Mention should also be made of specific ulcers of the stomach, due to tuberculosis and syphilis, and possibly, like simple ulcer, leading to hæmorrhage and perforation. (5) It not rarely happens that cancer grafts itself on an ulcer of the stomach. (6) The pathogeny of gastric ulcerations is not yet completely cleared up. Infectious agents, toxic agents, arterial lesions, and changes in the gastric juice, must be taken into account. It is possible that an ulceration, quite small at first, may end in ulcus simplex. (7) The treatment of gastric ulcerations is, according to circumstances, medical, specific, and surgical.

(145) Nasal Crises in Tabes.

Henri Jullian (*Rev. de Méd.*, July 10th, 1900) recounts what he states is the second case of nasal crises in tabes to be described. In the previous instance recorded by Klippel, the crises appeared in the third year of the disease. There was diminished sensibility of the nasal mucous membrane, and on the left side a lessened sense of smell. The crises were preceded by a sort of aura, a curious sensation limited to, or more marked on, the left side of the face, particularly the cheek, and accompanied by hyperæsthesia of the affected region. Then followed a sensation as if the left nostril were stuffed up, and a prickly feeling round the larynx; finally, there was a violent fit of sneezing, which terminated the crisis and the abnormal sensations in the region of the fifth nerve. In Jullian's case, a patient in the fifth year of the disease, there was no aura, but merely a prolonged bout of sneezing, preceded by irritation of the mucous membrane, and unassociated with any increase in the nasal secretion. There was some permanent anæsthesia of both cheeks, which was complete on the sides of the nose; there was total anosmia and some diminution in the sensibility of the nasal mucous membrane.

SURGERY.

(146) Pathogeny and Treatment of Abscess of the Liver.

In the Section of Surgery at the recent International Congress of Medicine, Dr. Giordano (Venice) introduced a discussion on this subject: Since 1884 he has operated on 72 cases of abscess of the liver. This, to his mind, proves that the affection is not purely exotic. Most of his patients have been alcoholics, and he believes that cirrhosis caused by alcohol predisposes to hepatic suppuration. In order to reach the liver the peritoneum must be freely opened up without interfering with the costo-diaphragmatic *cul-de sac*. The liver having been exposed is carefully isolated from the rest of the peritoneal cavity by means of sterilised compresses; there then remains nothing but to incise the abscess and establish drainage without washing out. Among his 72 operations he had 42 cures and 30 deaths, the fatal result in most of these occurring after operations that had been too long delayed.—Dr. Adamidi (Cairo) said that alcoholism evidently plays a predisposing part in the production of liver abscesses; the determining cause, however, is an ascending angiocholitis of intestinal origin. A certain number of cases of spontaneous cure following rupture of the liver abscess into the bronchi have been recorded. On the other hand, said the author, how many deaths have been due to this mode of termination? The only treatment of hepatic abscess, according to him, consists in wide and early opening by the slow procedure, which certainly gives better results than when the operation is completed at once. When the abscess is situated very high it can easily be reached by resection of ribs.—M. Hache (Beyrout) expressed the belief that ultimately Little's method, although so "seductive," would be completely abandoned. It was seldom indeed that there existed adhesions sufficiently resistent to protect the large peritoneal cavity, and the existence or absence of such adhesions could by no means be foreseen. He said that for his own part he could cite 2 cases of death from peritonitis that were distinctly consecutive to rapid opening by Little's method. The best means of avoiding infection of the peritoneum was preventive suture of the liver to the abdominal wall.

(147) Intracranial Resection of the Trigeminal Nerve.

In the Section of Surgery at the recent International Congress of Medicine Professor Fedor Krause (Berlin) gave details of 24 cases of intracranial resection of the trigeminal nerve and their results. He said that intracranial resection of the branches of the trigeminal nerve was not certain in its result; therefore when opening of the skull appeared to be indicated, extirpation of the Gasserian ganglion and of the trunk of the trigeminal nerve should be performed. He had performed this operation 24 times in patients from 30 to 72 years of age, and had always used the temporal method devised by him in 1892. A woman, aged 58, who was extremely exhausted, died of collapse, and a man aged 72, died on the sixth day after the operation, owing to sclerosis of the coronary arteries and cardiac insufficiency. In this case the wound had healed by first intention without fever. Of the first patients operated on there were still living a woman aged 75 and a man of 62 on whom the operation was performed seven and a-half years ago; a woman aged 76 and one of 53 operated on six years ago; a woman aged 42 operated on five years ago; and one aged 50 operated on four years and three months ago. All these patients had remained free from pain up to the present time. The advantages of the operation were in Krause's opinion so great that notwithstanding the dangers attending it, it would keep the place it has gained. These cases of very severe neuralgia very frequently lead to attempted suicide on account of the terrible suffering.

(148) Tropical Phagedæna.

In the Section of Tropical Medicine at the recent International Congress, Dr. Le Dantec, Médecin de 1e Classe of the French Navy, and Professeur-Agrégé in the Medical Faculty of Bordeaux, presented a communication on tropical phagedæna. He defined the condition as a complication of wounds characterised by the presence of a [illegible] membrane which transformed a simple [illegible] into a spreading sore. He was inclined to regard it as identical with the condition described in temperate climates under the name of hospital gangrene. The pathogeny of phagedæniculcer in natives warranted the belief that the natural habitat of the microbe was not the hospital but moist earth. In the soil there were found three microbes that were dangerous to wounds in man: the septic

vibrio, the tetanus bacillus and the phagedænic bacillus. These general considerations were of the greatest importance to medical officers who accompanied expeditions.

MIDWIFERY AND DISEASES OF WOMEN.

(149) Early Tubal Pregnancy: Difficulties in Diagnosis.

Toth (*Centralbl. f. Gynäk.*, No. 38, 1900) publishes two cases which seem to show that extrauterine gestation is even commoner than is now suspected, and that pelvic inflammation, often its cause, may mask its earlier stages completely. The first patient had been treated for a protracted period for extensive inflammatory exudation in the pelvis. After antiphlogistic measures it partially disappeared, and then a well defined bilateral tumour was discovered. At the operation a tubo-ovarian cyst was found on the left side, and on the right a dilated tube, distended with blood, and a small hæmatocele. Chorionic villi were detected in the right tube. The history of the case gave no indications of the possibility of tubal gestation. In the second case abdominal section was performed for a bilateral tumour; as in the first, no evidence of pregnancy of any kind was to be obtained. An ovarian tumour was removed, and on the opposite—the left—side a distended tube, full of clot, was found. Its ostium opened into a great mass of clot in Douglas's pouch. Chorionic villi were detected in the tube. Both patients recovered.

(150) Cocaine in Midwifery.

Marx, of New York (*Medical News*, August 25th, 1900), has tried with success the method of injecting small doses of cocaine solution into the spinal canal in cases of labour, the cases (eight in number) being very gratifying as to results. The method was used to promote analgesia during labour, and without danger to mother or child. The cases thus treated were all at the New York Maternity Hospital. The patient's back (lumbar region) being thoroughly disinfected, the patient lay on the side with the back arched. The thumb of the left hand was placed on the spine of the fourth lumbar vertebra. A needle about 4 inches long was employed with a metal hypodermic syringe, both of which had been boiled 10 minutes. The needle was inserted half an inch in front of and just outside the edge of the thumb at an angle of about 165°, the direction of its entry being upwards and slightly towards the middle line. If the point of the needle struck the lamina (of the vertebra), it is to be moved gently up or down until the space between the vertebræ was felt. The puncture is made between the 3rd and 4th, or between the 4th and 5th vertebræ. The point is slowly pushed in until cerebrospinal fluid is seen to run out. Ten minims of a cocaine solution representing ⅛ gr. are now injected, and the needle withdrawn. Labour pains in these cases proceeded without pain, total analgesia being present below the level of the umbilicus. The uterine contractions took place as usual during and after the birth of the body. In some of the cases the patient suffered from headache and slight elevation of temperature the day after the injection, a condition noticed also in surgical (non-parturient) cases. Dr. Marx states that as the above experience was limited to eight cases and no danger was apparent, it would be well to try the method in cases of prolonged labour, adding that the patients were exceedingly grateful for the complete relief of pain and suffering during their labours. Burman and Kreis (*Semaine Médicale*, July 18th, 1900, report six cases (five being primiparæ) also with good results.

(151) Primary Cancer of Fallopian Tube.

Novy (*Monats. f. Geburts. u. Gynäk.*, June, 1900) publishes a full report of a case under the care of Pawlik of Prague. The patient was a widow, aged 70, she was extremely fat, and had pendulous abdomen. She had borne ten children. Cancer of the vagina was diagnosed, but nothing more than colpitis granulosa detected. Sanious discharge was distinctly noted. The curette being used, a piece of tissue was removed which bore the character of adeno-carcinoma; but at every other point on the endometrium that was scraped the tissues only showed evidence of endometritis glandularis. Hysterectomy was performed on August 11th, 1896, Pawlik reserving publication till a sound after-history could be obtained. The vagina was divided around its attachment to the cervix, but the uterus was not freely movable, and could not be drawn downwards. An abdominal incision was therefore made. Then a tumour was detected. It consisted of the right tube. The uterus was removed, together with the right appendages; the ligatures, excepting one applied to the right ovarian vessels, were drawn down into the vagina. The vaginal wound was closed and the abdominal wound drained, because the patient was so fat. Recovery from the operation was complete though slow. The patient enjoyed two years' complete immunity, then recurrence set in, causing death in five months. The tube was quite healthy in its inner or uterine third, and the remainder was the seat of cancer, apparently malignant degeneration of a papilloma. The malignant deposit in the endometrium was secondary.

(152) Extrauterine Pregnancy: Twisted Pedicle.

Pozzi (*La Gynécologie*, June 15th, 1900) reports a case where the patient ceased to menstruate after the beginning of last January. On the 19th of that month she was seized with sharp abdominal pain with show of blood. The pains and metrorrhagia continued till an operation was performed on April 2nd. At that date the cervix was large, soft, and patulous. The body of the uterus was anteflexed, and above and to the left was a mass as big as a fœtal head, and of the consistence of a fibroma. On opening the abdomen a very dark tumour was detected; it looked as though it were an ovarian cyst with twisted pedicle. It was covered above with adherent omentum, and was found on careful scrutiny to be a distended right tube twisted over to the left. The pedicle was twisted a whole turn from right to left. The tumour weighed under ¾ lb. It contained a fœtus of the third month, of normal development, dead, but not macerated. The outer part of the left tube was obliterated. Pozzi made an artificial ostium. The patient recovered.

(153) Single Placenta in Case of Triplets.

Saniter (*Monats. f. Geburts. u. Gynäk.*, June, 1900) recently exhibited before the Berlin Obstetrical and Gynæcological Society a single placenta which was delivered after the birth of three infants, all males and all breech presentations; they measured each about 12 inches. All died shortly after birth.

THERAPEUTICS.

(154) Cacodylate of Iron.

In the Section of Therapeutics at the recent International Congress of Medicine, Dr. P. Lereboullet (Paris) said that cacodylic medication in the form of cacodylate of soda having proved useless as a remedy for chlorosis and chloranæmia, Dr. Gilbert and he had used cacodylate of iron in the treatment of these affections. They injected under the skin ferric cacodylate, a very soluble and only slightly toxic salt, in a solution dosed at 3 cg. per c.cm.; they also gave it by the mouth in the form of drops to be taken before meals. The daily doses varied from 3 to 10 cg. hypodermically, and from 5 to 30 cg. by the mouth. Both methods of administration proved to be alike free from inconvenience. In no case have they observed local or general disturbances; in particular there have been none of the renal complications which are so frequent after injection of other iron salts. Cacodylate of iron is indicated in affections where one has at the same time to counteract the diminution in number of the red corpuscles, and the fall in the amount of hæmoglobin (chlorosis, chloranæmia, lymphadenia, leukæmia). Tuberculous chloranæmia, provided the pulmonary lesions are not too far advanced, seems to be specially benefited by this treatment, which has never caused congestive phenomena or hæmoptysis. Albuminuria, which is frequent in such patients, is not a contraindication but rather the contrary. In 5 cases the kidney lesions underwent marked improvement after the injections.

(155) Hypodermic Injections of Phosphate of Lime in Pulmonary Tuberculosis.

In the Section of Therapeutics at the recent International Congress of Medicine, Dr. G. Angiulli (Naples) read a paper on this subject. He said the principle of the treatment was to place the diseased organism in a position to repair

the losses of phosphate of lime, which take place from the commencement of the disease—sometimes even before it shows itself, constituting in such cases what has been called pre-tuberculous phosphaturia. With the object of repairing this daily loss most rapidly and in the most surely assimilable form, he gives hypodermic injections of phosphate of lime. In slightly advanced cases of slow progress he has seen after some months of treatment the general resistance greatly increased. The patient gains weight, menstruation which had stopped comes on again, and by degrees all the symptoms of the disease disappear—even at last fever, so that from the clinical point of view the patients may be looked upon as cured. In very advanced cases with numerous cavities and hectic fever he has seen the strength regained to such an extent that patients too weak to move were able after twenty or thirty injections to go out. At the same time the symptoms, with the exception of fever, have subsided, but the malady, though rendered slower and milder, has nevertheless continued to progress. In such cases Dr. Angiulli, a few months ago, began to use inhalations of finely-powdered oxide of lime; these are used several times a day for a variable length of time according to tolerance. Though too short a time has elapsed for any complete result to be recorded, Dr. Angiulli is able to state that the patients have readily become habituated to the inhalations, and that their condition shows remarkable improvement. Analysis of the urine made every day has proved that the phosphate of lime given hypodermically is completely assimilated; under its influence the quantity, which was increased before treatment, has gradually diminished till it has reached the normal standard. The good results which the author claims for the treatment have been obtained without any alteration in the hygienic conditions—sometimes very bad—or in the diet of the patients.

(156) The Intensive Use of Guaiacol in Pulmonary Tuberculosis.

In the Section of Therapeutics at the recent International Congress of Medicine, Drs. Weill and Diamantberger (Paris) presented a communication on this subject. They claim to have been the first in France to use guaiacol in hypodermic injections. For the last eleven years they have employed the method, and they have now a record of more than 500 cases treated and considerably ameliorated by the systematic use of guaiacol. The failures which have been experienced by other practitioners depend (according to the authors) on: (1) The inferior and variable quality of the liquid, so-called commercial, guaiacol. The authors use the synthetic crystallised guaiacol, a substance which they describe as very antiseptic, anæsthetic, and non-toxic; it may be given in a daily dose of 3 grams, and even 4 grams without fear of reaction or intoxication; (2) the very small quantity used. The formulæ of Picot and Pignol—1, 2, and 5 per cent.—are quite insufficient, all the more as there are added iodoform, which causes diarrhœa; eucalyptol, which is an irritant; and carbolic acid, which is a caustic. The authors use the following formula: ℞. Crystallised guaiacol: oil of sweet almonds sterilised at 120°, āā 10 grams; hydrochlorate of cocaine 20 centigrams; this is dissolved in an equal quantity of water and kept in a dark bottle. A daily hypodermic or intramuscular injection of 1 c.cm. is given in the gluteal region. Besides the injections they use: (*a*) Painting the different parts of the chest wall with the same solution every night over a space of 8 to 10 square centimetres; (*b*) enemata of 100 grams of tepid milk, to which 40 or 50 drops of the same solution have been added; (*c*) pills of the following composition: ℞. Crystallised guaiacol 1 centigram, crystallised terpin 2 centigrams, benzoic acid 3 centigrams, extract of belladonna, extract of hyoscyamus, āā 1 milligram; to make one pill; mitte 100; one to be taken every three or four hours. The "intensive and daily guaiacolisation," combined with hygienic and dietetic treatment, should be continued for several months, with interruptions of eight or ten days every three weeks. The symptoms that are most beneficially influenced by the treatment are, in the order of their importance: Expectoration (in respect of amount and fœtor), cough, hæmoptysis, fever, night sweats, diarrhœa, and general debility. Intensive guaiacolisation is indicated in all forms of pulmonary tuberculosis, in chronic bronchitis with abundant expectoration, in pulmonary gangrene, and in intestinal tuberculosis.

(157) Diet in Albuminuria.

In a paper on this subject read in the Section of Therapeutics at the recent International Congress of Medicine, Dr. A. Robin (Paris) said: It is recognised that the same system of diet is not suitable for all sufferers from Bright's disease. In particular the exclusive use of milk causes in some of them an increase, at least for a time, of albumen in the urine. Further researches prosecuted for many years have convinced him that an exclusive milk diet diminishes albuminuria always less than a vegetable diet, sometimes even less than the use of meat alone. In all cases a mixed diet of milk and vegetables or of milk and meat has a better effect than the exclusive use of milk. The following is the system that he adopts for the purpose of ascertaining the regimen most suitable for each patient. He begins by giving only milk. This has the effect of first increasing the amount of albumen in the urine; then it diminishes, and remains stationary. At this stage vegetables are added to the diet. New oscillations are then produced; when these have ceased meat is cautiously allowed, whilst milk and vegetables are continued. In this way it is easy to ascertain which of the three systems of diet—milk, milk and vegetables, or milk, vegetables and meat—brings about the most marked diminution in the amount of albumen eliminated. It is important, also, to ascertain the value of each alimentary substance in regard to the production of albuminuria. Some researches which Dr. Robin has made on this subject have led him to the following conclusions: Bread has no effect on the albumen; wine causes an increase; amongst meats, beef and veal are more to be recommended than mutton or fowl; fish should be forbidden.

(158) Hepatic Opotherapy in Diabetes Mellitus.

In a communication on this subject, presented to the Section of Therapeutics at the recent International Congress of Medicine, Dr. Gilbert said: The ingestion of liver substance modifies, in a certain number of diabetic subjects, the amount of sugar excreted. But the effects observed differ considerably in different cases. Sometimes hepatic opotherapy causes diminution or disappearance of glycosuria; sometimes on the contrary it has no appreciable influence thereon, whilst in certain cases it undoubtedly increases the amount of sugar. It is easy to assure oneself that the cases in which the administration of liver substance brings about improvement are those in which the diabetes is connected with a functional inadequacy of the liver (characterised by diminution of urea, urobilinuria, etc.) On the other hand, cases of diabetes that are not benefited or are even made worse by the treatment, are those in which the glycosuria appears to depend on over-activity of the organ. This kind is more frequent than the others; it is generally hereditary, and is accompanied by increased size of the liver, with structural integrity of the organ, considerable elimination of urea, etc. Therefore hepatic opotherapy in diabetes mellitus is not only a therapeutic method useful in a certain number of cases, but also a diagnostic procedure which, in connection with other signs, allows the clinician to differentiate diabetes due to functional activity from forms of the disease due to over-activity of the liver.

(159) Therapeutic Use of Thymus.

In the Section of Therapeutics at the recent International Congress of Medicine, Dr. Blondel (Paris) read a paper on this subject. He said it was generally admitted that chlorosis depended on an auto-intoxication, in the production of which the absence, or at least the insufficiency, of the internal secretion of the ovary played an important part. Hence was derived the idea of administering preparations of ovary as a remedy for that affection. Previous researches having satisfied Dr. Blondel that there was an almost absolute functional analogy between the thymus and the genital glands, he conceived the idea of employing preparations of thymus instead of ovary in the treatment of chlorosis. In 15 patients treated in that manner he had seen marked amelioration of the general condition take place within a few weeks, whilst

at the same time appetite and sleep returned, the colour was restored, the number of red corpuscles was notably increased, palpitations and jugular *bruit* disappeared. In addition to this, Dr. Blondel followed up the researches of Owen on the administration of thymus in Graves's disease. He had treated in this manner 4 patients with very satisfactory results. In a few weeks the circumference of the neck diminished by several centimetres, the pulse fell from 120 or 130 to 80, tremor became less, etc. Lastly, in 10 nurslings in whom development was slow and imperfect—in some owing to premature birth, in others to congenital debility—the administration of thymus caused a regular rise in the weight curve which till then had been stationary or even on the down grade. In all these cases he used lamb's pancreas, which is much cheaper than that of the calf. In order to prevent any feeling of disgust he first peptonised the thymus. He gave his patients from 1 to 2 grams of thymus peptone daily. A peptone of ordinary meat given to the same patients in equivalent doses produced no appreciable effect.

---

(160) Treatment of Aneurysms of the Aorta.

IN the Section of Therapeutics at the recent International Congress of Medicine, Dr. Golubinin of Moscow, said he had employed in 8 cases the method of treating aortic aneurysms by injection of gelatinised serum recommended by Lancereaux and Paulesco. The number of injections varied according to the case from 2 to 15. Of the 8 patients 4 died in a short time and the other 4 were lost sight of; in 3 of the cases belonging to the latter group the injections produced no effect. In the remaining one they were followed by slight improvement in the subjective symptoms without modification of the objective signs. Dr. Golubinin had come to the conclusion that the method did not fulfil the expectations that had been founded on it.—Dr. Huchard said: In the treatment of aortic aneurysms it is a mistake to allow oneself to be hypnotised by the changes to be brought about in the contents of the sac, that is to say, in the blood, and to take no account of the containing structure. The method of gelatinised injections, which is useful, although insufficient, is open to this criticism. To complete its action, especially in persons with large heart and increased arterial tension—they are almost always at the same time subjects of Bright's disease—medicaments should be chosen which diminish arterial tension, such as potassium iodide, trinitrine, nitrite of amyl, and especially tetranitrate of erythrol, or tetranitrol, which Dr Huchard has now used for a considerable time and which, as compared with trinitrine, has the advantage of a more durable action. Moreover, an essential point is to supervise the diet not in regard to quantity, as in Valsalva's method, but in regard to quality. Meat, which holds too large a place in our food, contains toxins, which have an excessively powerful vaso-constrictor action. The best treatment of aortic aneurysm is still absolute milk diet regularly adhered to.

---

(161) Artificial Foods.

PROFESSOR A. JACOBI (New York) read a communication on this subject in the Section of Therapeutics at the recent International Congress of Medicine. He said: The results of the analyses of human milk are contradictory; no two are alike. Alterations in different periods of lactation which are asserted by some are denied by others; those caused by menstruation, sickness, or ingesta are either well understood or dimly appreciated but rarely measurable. The nature of its proteid, whether uniform or compound, is not sufficiently known. Whether there is an essential quality that is beyond the domain of chemistry is not known. That is why so many and so different ironclad rules have been established for the selection of substitutes, and why the uncertainty has rendered experimentation with commercial substitutes, by chemists and even by respectable clinicians, so common. If human milk were a uniform body, the demand for an exactly equivalent substitute would be justified. Nature, however, is more liberal in allowing latitude than a chemist. Heat both improves and injures milk. When milk is exposed to 68° to 70° C., ten or fifteen minutes' heat destroys the bacterium coli and bacillus lactis aërogenes; after long exposure it kills pathogenic germs; at 80° C. it coagulates albumen and changes the taste and odour of the milk. Even at 70° C. it changes casein so as to impair its value for dairy purposes. In boiling, a part of the albumen is deposited, the lecithin is destroyed, the fat altered both chemically and physically. Serious changes appear to take place, through long boiling, both in casein and nuclein. High temperatures continued for hours are required to destroy some of the long-lived spores; their injuriousness, however, is not entirely clear. Boiled, pasteurised, or sterilised cow's milk is never woman's milk; it is not a curative agent; it presents, however, the great advantage of destroying fermenting and pathogenous germs; that is why it is indispensable in large cities and during the prevalence of certain epidemics, and wherever fresh and unpolluted milk is not accessible. When employed as exclusive infant food, cow's milk, watered or not, is liable to cause constipation, or diarrhœa, rickets, and scurvy. To preserve its antibacterial effect heat should be followed by immediate and rapid cooling, but not freezing. Ample dilution of the artificial food of the infant, and particularly of the newly-born, is required because of the heterogeneous composition of cow's milk; even those who are as usual put to an incompetent breast require water to combat loss of weight and the tendency to nephritis and to nephrolithiasis, the former of which is still more frequent than the latter—indeed, very frequent. A large amount of liquid does not interfere with the motility of the stomach and does not cause dilatation — first, because the normal infant is no glutton, and secondly, because absorption begins at once. Easy and equal digestibility of the casein in woman's and in cow's milk is either asserted or denied by good observers. When cereal decoctions are mixed with cow's milk, its casein is claimed and proved to precipitate in fine tufts. On the other hand, cereals are said to have no such effect any more than water. Water, however, is recommended by the same authors as addition to cow's milk. This contradiction is met by those who recommend dextrinised flours for the dilution of cow's milk. The digestibility of a certain amount of amylum, such as is contained in cereals, has been erroneously and persistently denied, when it had long been proved both by experience and by experiments to exist. Cereal decoctions are the proper diluents for the surplus casein of cow's milk. Milk sugar is partly absorbed in the stomach, partly in the intestine, partly changed into lactic acid. It is required for digestion, and is an antiseptic. Not enough of it, however, can be given to have the latter effect to the same degree that is exerted by flours. Besides, milk peptones disappear with acid fermentation. That is why milk sugar should not be given in large quantities, but other carbohydrates in its stead. Cane sugar should take its place particularly, as for the purposes of digestion there is milk sugar enough in cow's milk that forms part of every artificial food, and because there is a ferment in the intestine of the young which inverts cane sugar and renders it absorbable. Besides, every other carbohydrate has the same power to protect albumen against putrefaction. Fat is added to cow's milk for the alleged purpose of increasing its nutritive property (by preventing the loss of the fat and albumen of the tissues), and by loosening and separating the minute particles of casein. It should be remembered, however, that even human milk contains often so much fat as to cause "fat diarrhœa;" that the normal infant fæces eliminate unchanged fat in goodly quantity; that, moreover, the fat globules of cow's milk are larger, less numerous, and less absorbable than those of woman's milk; that the two fats are not equal chemically; and that the urine is liable, after feeding with cow's milk fat, to contain ammonium and the gut toxins. The mineral constituents of cow's and human milk are different. The addition of chloride of sodium to artificial foods is required both for physiological and chemical reasons. Home-made artificial foods are preferable to the proprietary foods of the market, for many reasons. The separation of the component parts of cow's milk by mechanical means, and the recomposition of the same, is a procedure of doubtful value. Experience of the physician and of the well directed public is equivalent at least to laboratory and library theories based on facts that are *sub judice*.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(162) Post-pneumonic Paralysis.

It has been recognised for some time that paralysis may occur after pneumonia. Janakief has made a special study of this subject (*Thèse de Lyon*, 1900). This author divides post-pneumonic paralyses into two groups—(*a*) early, (*b*) late. In the first group the paralysis appears at the beginning or during the course of pneumonia, and is usually of a monoplegic type, sometimes hemiplegic, rarely paraplegic. The hemiplegic type has been particularly noticed by Charcot and Vulpian. In the second group are included cases which appear quite at the end of the disease or during convalescence. The forms are very variable, being sometimes paraplegic, crossed, purely localised, or ascending paralysis of the paraplegic type. The author quotes Boulloche as stating that these forms of paralysis are essentially marked by their diffuseness, their liability to affect the lower limbs, and, in the great majority of cases, by their curability. They differ absolutely in their course from permanent forms of paralysis due to other causes. According to Janakief's investigations they are apt to follow severe attacks of pneumonia, especially when epidemic in form. According to this writer the most frequent period for their appearance is within a fortnight of the crisis, although an earlier occurrence is not exceptional. The first thing which the patient may complain of is itching, tingling, a certain degree of numbness in the limbs, or a sensation of cold in the legs or arms. In some, mydriasis or ptosis may be the first symptom, with a feeling of constriction in the pharynx with difficulty in swallowing. There may be pain in the back of the neck, also paralysis of the palate. Very frequently the legs are attacked first, afterwards the arms. In other cases the paralysis may remain localised in an arm or leg. In a short time symptoms become more marked, the legs become flexed and do not respond to voluntary stimulus. The grip becomes enfeebled, and objects are allowed to drop; the fingers become flexed in the palm and immovable. Walking becomes more and more difficult, and the patient is obliged to take to bed. Frequently these paralytic phenomena are accompanied by more or less pain, especially in the neighbourhood of the joints. Alterations of sensation are very slightly marked. Muscular atrophy is usual, but varies considerably in its intensity. Although it is usually located in the limbs this form of paralysis may affect other parts such as the palate and ocular muscles internal and external. The occurrence of post-pneumonic paralysis is essentially low. In ocular cases there is progressive improvement in all the symptoms, and, in fact, in the majority of cases recovery is complete. The duration varies. Some cases have lasted from 12 days to 3 or 4 weeks, others 2, 3, 7 or 12 months. In some exceptional cases death is due to generalisation of paralysis extending to the bulbar region. These paralyses are grouped under the class of polyneuritis, but, so far, the lesions present have not been exactly determined, and it may be supposed that they are due to the action of pneumonia toxin on the ocular or peripheral nerves. The prognosis depends, therefore, on several factors; the nature of the pneumonia, the form and seat and extent of the paralytic lesions. The most severe form of post-pneumonic paralysis is that which, beginning in the lower extremities, increases rapidly in intensity, invading the muscles of the thighs, the abdomen, the thorax, and the upper limbs. It subsequently involves the muscles of the larynx, pharynx and tongue. This is, in fact, a form of acute ascending paralysis. It is also uncommon to meet with fatal cases of pneumonic myelitis. It may be stated, therefore, that with some exceptions post-pneumonic paralysis is a form of peripheral neuritis which tends to recovery. There is no special form of treatment required, the measures in use in other forms of polyneuritis being indicated.

(163) Neuritis following Malaria.

Sacquépée and Dopter (*Rev. de Méd.*, April, 1900) give a summary of all hitherto published cases, and in addition record 3 of their own. A colonial administrator had an attack of malaria when 41 years old. During the following ten years he had periodic attacks. When 51, he became enfeebled, and complained of shooting pains in the joints and right hypochondrium. The pain over the hepatic region became fixed, and fever, sweatings, vomitings, and gastric troubles followed. There was also intestinal colic, severe and continuous diarrhœa, and the urine was loaded with urates and biliary pigment. On admission to the hospital when 52, there was paresis of the lower limbs with intense pains in the joints. The pains followed the course of the sciatic nerve, and were most severe during the night. Sensibility was diminished, and the muscles atrophied. Over the hepatic region there was superficial and deep pain, and the skin was hyperæsthetic but not œdematous. A diagnosis of hepatic suppuration was made, and laparotomy was performed. The liver was found to be very enlarged and hard, but although numerous exploratory punctures were made, there was no fluid or pus to be found. After the operation the trouble in the hypochondrium ceased, but torturing lancinating crises occurred in the arms, the pains gradually extending to the thenar eminence and fingers, and being accompanied by rapid atrophy of the thenar and interosseous muscles. The palms were hyperæsthetic, and the skin covering the hands "glossy." The lower limbs became œdematous, albuminuria and coma followed, and death occurred three months after admission. The necropsy revealed slight tuberculous lesions in the lungs, and degeneration of the median and sciatic nerves. These were examined in osmic acid, and there was scarcely a healthy fibre left. The axis cylinders had disappeared, and only drops of myelin and a few nuclei remained. The liver was enlarged and hard, but there was no hepatitis. In two other cases treatment consisting of rest, electricity, massage, warm baths, quinine, and antipyrin produced considerable improvement. The authors have restricted their choice of cases to those of which the malarial origin was absolutely incontestable. The cases are of considerable interest in regard to conditions frequently met with in patients who have resided in tropical climes, and the subject is not without importance in insurance work.

(164) Senile Bronchitis.

R. W. Wilcox (*Amer. Journ. Med. Sci.*, cxix, May, 1900) points out that the tissue changes of old age are chiefly of the nature of (1) pure atrophy of the constituent elements of the tissue; (2) a progressive infiltration into certain tissues of organic (fatty or albuminous) or mineral (calcareous) elements foreign to their normal condition; and (3) an exaggerated production of connective tissue. All these changes can be found in the chest contents of the aged, and produce a modifying effect upon the clinical characters of senile bronchitis. The disease always tends to become chronic, because senility follows the same course. The amount of expectoration must be lessened, and here belladonna, which does so much for children, generally fails, and strychnine and ammonium carbonate are to be recommended. Opium and its alkaloids should not be given, for "they simply drown the patient in his own secretion." Systematic massage yields the most brilliant results; it increases chest expansion, improves nutrition, and facilitates expectoration and also diminishes the amount of sputum.

SURGERY.

(165) Hernia of Bladder through the Pelvic Outlet.

Harrington (*Annals of Surgery*, September, 1900) publishes an interesting case of hernia of the bladder through the pelvic floor from the traction of a large recurrent subperitoneal fibroma. The subject of this very rare affection was a single woman, aged 46. The fibroma [illegible] had its origin in the subperitoneal tissue in front of and to the left side of the bladder, and in its growth had evidently pushed through the fibres of the levator ani. This tumour was removed in 1893. Six years later it had again developed to a great size, and was so attached to the bladder that by its weight it had drawn this organ through

a gap in the levator ani, producing a vesical hernia and complete retention of urine. The hernia, which was a para-peritoneal one, involved almost the entire bladder, the portion remaining in the pelvis being drawn into a narrow tube by the traction of the tumour. The author decided that an abdominal operation would be the most feasible method for the reduction of the hernia and the removal of the tumour, but an attempt in this direction having failed, an incision was made from the tuberosity of the ischium to the upper part of the labium. This exposed the tissues of both the anterior and posterior tumours, which arose from a common base. It was difficult at first to distinguish the bladder wall from the fibrous tissue of the tumour. The bladder, having been distended by air, could be readily deflected from the tumour, and was then pushed back into the pelvis through the opening in the floor of this cavity. The tumour itself was then cut away from the attachments to the skin and subcutaneous tissues. As the bladder showed a marked tendency to prolapse again an attempt was made to prevent any further escape by using the uterus as a plug. Such step was justified, the author holds, by the age of the patient and repeated attacks of severe uterine hæmorrhage. The appendages having been removed on both sides, the fundus of the uterus was drawn down to the gap in the levator ani muscle and fixed there by a ligature. The patient made a good recovery and since her convalescence the vesical function has been properly performed.

(166) Removal of Fibroma of Mesentery.

LEXER (*Berl. klin. Woch.*, No. 1, 1900) reports a case in Von Bergmann's wards. The patient was a strong man, aged 41. He was in good health till last April, then attacks of dragging and colicky pains came on, lasted for weeks, and disappeared. A very hard tumour was detected, but he declined operation for several months. At the end of that time the tumour was spherical, as big as a child's head, and clearly circumscribed, excepting below, where it seemed as though fixed to the pelvis. Above it reached to the umbilicus. Lexer specially notes that it could only be moved slightly and from side to side until the patient was put under chloroform. Then its mobility was extreme; it could be pushed up from above the symphysis to over the level of the umbilicus, and it could also be rolled into either flank. On October 12th, 1899, Lexer operated. The tumour lay completely engaged in the mesentery, yet with a distinct pedicle consisting of the part of that fold nearest the spine. Enucleation was impracticable, and as it was not certain that the tumour was innocent, that operation was not attempted. Some very large mesenteric arteries and veins were secured in the pedicle, and then the tumour with its mesenteric capsule and about 6½ feet of small intestine connected with that segment of the mesentery were cut away. Lexer believed that a circular suture or a Murphy's button with end-to-end anastomosis would alike be objectionable. He therefore practised lateral entero-anastomosis, and the severed ends of intestine were sucessfully united. The patient was able to leave his bed in three weeks. Six weeks after the operation he could eat ordinary diet, and felt no local pain. The tumour weighed 5 lbs., and was 9¾ inches wide at its greatest diameter. It was a pure fibroma, with signs of mucoid degeneration at certain points.

(167) Ankylosis of the Spine.

CANTANI (*Il Policlinico*, f. 8, September 1st, 1900) reports some cases of idiopathic ankylosis of the spine (spondylosis rhizomelica), and discusses the subject generally. The cases are distinguished by a more or less complete rigidity of the whole or part of the vertebral column, without deformity. Sometimes the neighbouring articulations are occasionally affected, namely, the hip, temporo-maxilary. But the small joints, for example, fingers and toes, are spared. The thorax may be affected. There is no evidence of marked nerve affection; what muscular atrophy exists is probably due to disease; there is never any reaction of degeneration. The disease usually attacks adults not far advanced in age, and shows a marked preference for males; it generally begins with pain in the spine, especially in the sacro-lumbar region. The prognosis *quoad vitam* is not bad, but as regards the disease itself is not at all promising. As regards etiology, little certain is known; some cases seem to be of rheumatic origin, others gouty, and possibly syphilis plays a part. Pathologically it appears to start as a fibrous arthritis of the articulation, going on to complete ossification of the ligaments. In treatment some benefit has been derived from the application of a seton on the most fixed part of the spine.

(168) Resection of the Pylorus.

RYDYGIER (*Centralbl. f. Chir.*, No. 32, 1900) reports the subsequent course of the case in which he performed his first operation for resection of the pylorus in November, 1881. The disease indicating such treatment was non-malignant ulceration that had spread from the pylorus to the pancreas, and necessitated also removal of a portion of this gland. The patient, a woman, now 42 years of age, has been in good health during the long interval since the date of operation. She has been able to attend to her domestic duties, has not found it necessary to restrict or alter her diet, and has given birth to five children, the oldest of whom, a daughter aged 17, is now living. In cases of ulceration and cicatricial stenosis of the pylorus the author is an advocate of resection against gastro-enterostomy, provided the patient be in a good general condition and the adhesions be not too extensive. His grounds for this preference are the frequency of the development of cancer in simple ulceration of the pylorus and its resultant scar, the occasional occurrence of serious hæmorrhage from pyloric ulceration after gastro-enterostomy, and the bad results which sometimes follow the latter operation in consequence of reflux of the intestinal contents into the stomach.

MIDWIFERY AND DISEASES OF WOMEN.

(169) The Danger of the Long-Tube Nursing Bottle.

WENDE (*Buffalo Med. Journ.*, lvi, 104, September, 1900) has made microscopic sections of unemployed rubber tubes taken from nursing bottles, and has found that their internal surfaces presented numerous imperfections peculiarly adapted to resist cleansing, to permit decomposition and the growth of germs, and to lead to the formation of toxic matter which would contaminate and poison the milk as it flowed through. There were elongated pits and sinuses which might be likened in their effects to bacteriological "breed ovens," and sometimes the tubes were constructed of more than one layer between which enormous spaces were frequently developed directly connected with the lumen of the tube by the pits and sinuses referred to. The material used in the manufacture of the tubes was also very porous. In this way there was produced a perilous combination of pits, sinuses, and porosities in which bacteria would be readily caught and retained. From the bacteriological examination of a used and infected piece of rubber tubing Wende was able to recognise a deposit of decomposing material coating the inner surface, and being thickest near to the nipple and glass tubing, it consisted of a coagulated casein with innumerable bacteria, including specially the bacillus acidi lactici, the staphylococcus pyogenes aureus, and the oidium albicans. Injected into guinea pigs the material caused rapidly fatal results.

(170) Extirpation of Septic Cancerous Uterus after Labour.

MITTERMAIER (*Centralbl. f. Gynäk.*, No. 10, 1900) operated on a woman who had been pregnant twenty-two times, eighteen times to term. This, her twenty-third, pregnancy ended by expulsion of a dead ovum at the fifth month; she was then 47. In searching for the placenta, cancer of the cervix was diagnosed. The pulse was 135, the temperature over 104°. Two fingers could be passed into the cervical canal. There was not much flooding, the placenta was retained. The uterus was emptied of its contents and then extirpated through the vagina. The uterine tissue was very septic. The serous coat was raised up by gaseous exudation at several points. The vaginal wound was closed with catgut sutures. The temperature fell to normal at once, the pulse remained rapid for a day longer. On the ninth day, when the uterus was exhibited at a medical society, the patient was doing well. In discussion, some doubt was expressed about the

sepsis being generalised as Mittermeier implied. The nature of the bullæ developed from the serous coat was also contested. Roesing, Staude, and Seeligman believed that they did not represent detachment of the peritoneum by septic gas, but were due to mechanical force during the preliminary extraction of the placenta.

(171) Amputation in Error of an Inverted Uterus.

Morestin (*Bull. et Mém. de la Soc. Anat. de Paris*, March, 1900) examined a woman, aged 67, suffering from acute vaginal hæmorrhage, which evidently arose from a fleshy mass distending the vulvar aperture. There had been hypogastric pain and sanious discharge for a few months. The mass was large, covered with sloughy shreds, and was pedunculated. Morestin took it for a malignant tumour developed in the fundus, or a polypus of the fundus undergoing malignant degeneration, which had caused inversion of the uterus. Placing the patient in the usual position, without chloroform, he divided what he thought was the pedicle, believing that the upper part of the mass above the line of section was a small inverted uterus; but he found a serous canal open on the cut surface of the supposed pedicle, and this canal was simply made by invaginated peritoneum. In fact, the greater part of the inverted uterus had been cut away. The patient experienced little pain when the knife passed through the uterus. Pressure forceps were applied to the divided uterine tissue, a strip of iodoform gauze was passed into the serous canal, and the vagina plugged with the same material. The forceps were then removed; there was no bleeding. In a few days high temperature set in and there were rigors, broncho-pneumonia at length developed, but the patient recovered. The new growth was a spindle-celled sarcoma almost sessile. It was bulky and had dragged the body of the uterus, which assumed the appearance of a thin cord or pedicle, hence the error.

(172) Perforation of Bladder in Ectopic Pregnancy.

Baatz (*Centralbl. f. Gynäk.*, No. 24, 1900) relates a case of high interest. The tubal sac opened into the bladder at the fourth month. Pieces of bone came away during micturition. By means of the catheter masses of a hard structure could be detected in the bladder. On the right of the uterus lay a tumour of the size of a child's head; it crepitated on pressure. Radiography proved a failure, but by the aid of the cystoscope bones were seen in the bladder. The urethra was dilated, and a number of bones, incrusted with salts, extracted. The ectopic sac was removed through the vagina without opening the peritoneum. A great mass of bones with inspissated pus came away. The cavity left behind was freely washed out with lysol and drained. Another piece of bone came away from the bladder during convalescence. A few months later the urethra once more had to be dilated for the extraction of five more pieces of bone. Slight incontinence of urine persists. Baatz finds 13 similar cases already reported.

THERAPEUTICS.

(173) Apomorphine as a Hypnotic without Nausea.

Douglas (*Merck's Archiv*, June, 1900) points out a fact little known to physicians, that apomorphine acts as a prompt and effective hypnotic if injected subcutaneously in doses of about one-thirtieth of a grain, more or less. The dose should be adjusted as to be large enough to produce sleep and small enough to avoid nausea, and this being only about one-third of the ordinary emetic dose it is quite harmless. Douglas claims to be the first to show its hypnotic value, the *Handbook of Materia Medica and Therapeutics* of Potter (1899) stating that though a derivative of morphine the drug is "neither hypnotic nor narcotic in any degree." In mild insomnia and in furious delirium it was found to produce sleep within 25 minutes. The sleep is refreshing and restful, and no disagreeable after-effects followed. If a delirious patient refuses to go to bed, apomorphine will cause him to voluntarily lie down in a few minutes, and sleep will follow. There is no possibility of a "drug habit" being formed, as it becomes a vigorous emetic if the dose be increased. There are no cumulative effects. The small hypnotic doses usually accelerate the heart's action slightly. It was accidentally discovered that it becomes inert if dissolved in a saturated solution of boracic acid, the action of the drug, both as a hypnotic and emetic, being then completely neutralised. During four years apomorphine was given to 300 patients, and the hypnotic effect failed, or was slight, only in 2 or 3 cases (idiosyncrasy). In such rare and exceptional cases it was also found that the emetic effect did not follow even large doses. Tilton has stated that when used as an emetic in croup it is followed by a decline in the fever. The drug is therefore recommended as a safe one, deserving widespread use.

(174) Hypodermic versus Intracerebral Injections of Antitetanus Serum.

Loeper and Oppenheim (*Arch. Gén. de Méd.*, April, 1900) published 5 cases of tetanus; 4 were treated with hypodermic injections of antitetanus serum, and recovered, while the fifth, who was treated, after being trephined, with injections of 10 c.cm. of the serum into each hemisphere, died. In one of the cases which recovered, tetanus followed the manual removal of a sloughing placenta after an abortion; the incubation period was short (eight days), the onset was very acute, and the condition appeared desperate. In all 360 c.cm. were injected during thirteen days. On the other hand, in the fatal case, though the incubation period was short, the symptoms before the intracerebral injections were not alarming. As no reliable conclusions could be drawn from 5 cases, the writers collected 203 more, 59 of which were treated with intracerebral and 144 with hypodermic or intravenous injections of antitetanus serum. The total mortality among the latter class was 35.4 per cent., and even among the more severe cases, with an incubation period not exceeding ten days, was only 43.8 per cent. In cases with an incubation period of eleven days or more, the mortality was only 16.7 per cent. These results were far superior to those obtained by intracerebral injections, which gave a totality among 59 cases of 73 per cent. Dividing these cases into severe and slight, according to whether the incubation period was less than or exceeded eleven days, the mortality for the first group was as high as 82 per cent., and for the second 60 per cent. Thus even among cases classified by their publishers as "subacute" the mortality was 60 per cent. as compared with 16 per cent. for cases treated by the hypodermic method. An analysis of the cases proves that those treated intracerebrally were on an average no more serious than those treated hypodermically, and that the statistics for the two groups are strictly comparable. Whatever may be the explanation of the divergence between these clinical results, and the experiments of Roux and Borrel on guinea-pigs, the fact remains that intracerebral injections are less efficacious than hypodermic, and may be actually harmful. Probably the actual injection is not so devoid of danger as most writers have asserted; small hæmorrhages or even large cavities containing clots have been found *post mortem* in the cerebral substance. In the writers' case there was a hæmorrhage the size of a small nut in the centrum ovale of one hemisphere, and in a case reported by Gibb in the British Medical Journal of July 1st, 1899, death took place eight weeks after the last intracerebral injection from a cerebral abscess. The intracerebral method should therefore be entirely abandoned. Although the hypodermic method has not been proved experimentally to be more than a preventive, its curative effect is proved clinically by (1) the recovery of severe cases which would from past experience have proved fatal without it, and (2) the immediate improvement in or even arrest of the symptoms, such as trismus and fever, in the less severe cases. The quantity of serum used and the number of injections given must be regulated by the case, and may range from a few c.cm. to a total of 3,000 c.cm. or more, 100 c.cm. being given daily in a severe case. Two other methods of administering the serum have been tried successfully, though in too few cases for any reliable conclusions to be drawn as to their real value. These, which consist of intra-arachnoid injections (3 cases with 2 recoveries) and intravenous injections (10 cases with 7 recoveries) deserve further trial in desperate cases. Indeed, the intravenous method may eventually prove the most suitable for all but slight cases.

(175) Potassium Iodide in Acne.

GALLOWAY (*Practitioner*, May, 1900) reports the case of a man suffering from acne vulgaris, who treated himself with a certain "blood mixture." A severe iodide rash was the result. This in time disappeared, but some pustules had to be incised. There was, however, no recurrence of the acne, and the author thinks that iodides are worth a trial in cases of acne if precautions are taken not to produce too severe a reaction, and to warn the patient what to expect. Potassium iodide as a cure for acne, especially acne indurata, was recommended in doses of 5 grs. thrice daily by Leviseur (*New York Med. Record*, November 11th, 1899). The drug should be discontinued when the local reaction occurs, or when there is iodine in the urine. When inflammation subsides the treatment should be repeated. Ichthyol soap and sulphur ointment are used in the intervals.

(176) The Relief of Lumbago by Acupuncture.

SIR JAMES GRANT has recently redirected attention, in the *Montreal Medical Journal*, July, 1900, to the value of acupuncture in the treatment of lumbago and other myalgias. He inserts some 12 or 14 small (No. 8) fine steel needles, their number varying with the extent of the part to be treated, from one-half to three-quarters of an inch into the muscular tissue through the skin, at a distance apart of from one-half to three-quarters of an inch, and allows them to remain *in situ* for one or two minutes. He has observed that although before puncture the painful muscles may be hard and tense they very soon relax, while the needles are in position, and become soft, pliable, and painless. The patients, although previously almost immobile on account of the pain, can walk about quite freely after they have been withdrawn. He seems inclined to connect the relief from the distressing symptoms with changes in the electrical potential of the muscle, induced by the introduction of the needles. After their removal the skin is sponged, and friction is applied with a rough towel.

(177) Rectal Injection of Cod-liver Oil in Tuberculosis.

ZEUNER (*Therap. Monats.*, June, 1900) recommends that in cases where cod-liver oil cannot be taken by the mouth it could be administered *per rectum* with advantage, and beneficial effects may be obtained by using for the purpose the partially digested oil in an alkaline or neutral emulsion. To 100 parts of cod-liver oil are added 20 parts of water, 2 parts of pancreatin, ⅔ part of sodium chloride, and ½ part of inspissated ox-gall. The mixture is well shaken up into an emulsion, digested for two hours, and warmed before being administered. An injection of 3 or 4 ounces may be given once daily, an hour after the bowels have been evacuated by a natural motion or by the use of a simple enema. The patient is placed in the knee-elbow position, and the prepared cod-liver oil emulsion is slowly injected. If the emulsion is slightly acid, it should be neutralised or rendered slightly alkaline before injection.

(178) Influence of Static Electricity on the Normal Body.

YVON (*Arch. d'Elect. Méd.*, June, 1900) has made a large number of experiments upon the influence of the electric bath on the elimination of urea and phosphoric acid, and its action upon respiration, circulation, and the body temperature. He immersed himself for two hours at a time in a bath supplied by a Wimshurst machine acting at a potential of 115,800 volts, and driven by an electric motor. When all causes of error, such as changes in the heart and respiration rate, had been as far as possible excluded, the author found that static electricity had little or no influence on the healthy body, thereby confirming the original opinion arrived at in 1855 by Duchenne.

PATHOLOGY.

(179) A New Bacillus of Vaccine Lymph.

NAKANISHI (*Centralbl. f. Bakt.*, Bd. xxvii., No. 18) describes a bacillus which he finds constantly present in vaccinia pustules and which he has experimentally investigated. This is present in the epithelial cells of the "vaccine-pulp" of calves, either as a rod-shaped form staining in a bipolar fashion or as a spherical or oval form taking the stain less perfectly. In the lymph from children on the other hand the rod form is not found but large round refractive organisms are present similar to those found in calf lymph, which are looked upon by the author as variation forms of the bacillus. Pure cultures of the bacillus were obtained on agar plates both from the calf lymph and from lymph drawn from seven days old vesicles on the arms of children. The organism grows best on solidified blood serum and resembles morphologically the diphtheria and the so-called pseudo-diphtheria bacilli; it is a facultative anaërobe. The younger forms are wedge or "candle-flame" shaped, others are rod shaped, and in old cultures club shaped and rounded forms are common. Experimental inoculations in calves and guinea-pigs were negative. In rabbits intraperitoneal inoculation was also negative in result, but ulceration is produced by inoculation of the cornea and in the epithelial cells of this round or oval bodies are found. These are identical with the bodies described by Guianieri and Pfeiffer in the corneal tissue inoculated with vaccine lymph and in the corneal vesicles in variola and which were considered by them to be probably protozoa. By inoculation of cultures of the bacillus into the arms of several children, a student, and himself, the author was successful in producing typical vesicles. Two other students gave no reaction; possibly they were immune. He argues that the described bacillus is in all probability the specific agent in vaccinia, but with regard to the round and oval forms found in the corneal epithelium he hesitates to decide whether they are really varieties of the bacillus so modified by the unfavourable site on which they are growing or whether they are degeneration foci in the epithelial cells themselves. The fact that somewhat similar shapes are found in old cultures seems to give countenance to the first view. Much evidence has been collected to show that the "protozoa" of Guianieri, the so-called "cytorrycytes variolæ," are characteristic and specific, and as the author has produced identical forms by inoculation of cultures of this bacillus, he deduces that the bacillus is characteristic of small-pox lymph, and in all probability the exciting factor in small-pox itself. Further, as the organism resembles the diphtheria bacillus, so he draws a parallel between this disease and variola clinically and pathologically, and finds close analogies.

(180) Trauma and New Growths.

WÜRZ has studied 713 cases of new growth in the Tübingen clinic with regard to their relationship to previous traumatisms. Of these, 219 were benign, 584 malignant. Of the former, only 5 presented a probable relationship to previous trauma, in 2 others the connection could only be said to be possible, giving an average of 3.12 per cent. Of 503 carcinomata, 8, or 1.5 per cent., were of traumatic origin: and of 82 sarcomata, 6, or 7.3 per cent. He summarises his work as follows: A single trauma only comes into consideration as an etiological factor in osteoma, carcinoma, and sarcoma, and can only be said to play an important part in the first and last of these. The statistics have not concerned themselves with cases of repeated trauma or chronic irritation, but only with those giving evidence of a single injury: in other words, the occurrence of new growth in ordinary scar tissue is the real subject of the study.

(181) Pericarditis in Bright's Disease.

CHATIN (*Rev. de Méd.*, June 10th, 1900) records a number of experiments on the pathogeny of pericarditis in renal disease. The question at issue is as to whether there is a special renal or uræmic pericarditis, or whether the complication is a mere septic incident of ordinary Bright's disease. In 3 fatal cases which Chatin investigated the pericardial effusion was always sterile, while the toxicity of the blood serum was constantly below normal, although the pericarditis was acute, subacute, and chronic in the 3 cases; these facts are all inconsistent with the uræmic hypothesis. The pleural effusion in a case was also hypotoxic. The author hence concludes that in spite of Bosc's case of secondary infection the pericarditis of Bright's disease is aseptic and sterile. He holds also that his investigations fail to support the idea of a toxic pericarditis in such cases.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(182) Acetonuria.

H. C. Geelmuyden (*Norsk. Mag. f. Laegevidensk.*, lxi, 705, July, 1900) understands by the acetone series the three substances known as oxybutyric acid beta, or $CH_3CH(OH)CH_2COOH$; acetono-acetic acid, or $CH_3CO\,CH_2\,COOH$; and acetone, or $CH_3CO\,CH_3$. He gives the name acetonuria to the state in which one or several of these bodies are found in the urine: and he believes that the oxybutyric acid beta is the most characteristic of the three, and always predominates in the most serious cases—as, for example, in diabetes. Acetonuria may be due to insufficient decomposition of hydrocarbons, or to insufficient supply of them in the food (alimentary acetonuria), or to the absence of the power to decompose them in the system (diabetes). Marked acetonuria in cases of diabetes is always a grave symptom, pointing to the supervention of coma, and Geelmuyden believes with Stadelmann that the coma is the sequel of an acid poisoning, and may be retarded by the administration of large doses of sodium bicarbonate. The question of the origin and mode of formation of the acetone series is still an unsettled one.

(183) Polyuria and Pollakiuria of Hysterics.

Jean Abadie (*Arch. de Neurol.*, March, 1900), of Bourdeaux, has published cases which might make a distinction possible between polyuria of hysterics and that due to diabetes insipidus, simple polyuria, traumatic, alcoholic, and other polyurias, etc. Case 1. A man, aged 43, was seen by Professor Pitres for troubles of micturition. Temperate habits, suffers from rheumatic pains. Mother neurotic, and has had attacks of *grande hystérie*. Patient's brother is rheumatic. In 1870, during the Franco-German war, he contracted a mild gonorrhœa without complications. Later he suffered from much exposure to cold and wet on board ship in a storm, and suddenly thereafter began to be affected with troubles of micturition—namely, frequent desire to pass urine, even with an empty bladder, which gradually became in a few days a very troublesome feature. The urinary stream became thin and threadlike, and surgical examination showed a complete patency of the urethra, and the total absence of any stricture. Patient is not syphilitic, and appears in good health. There is a large erythematous patch on the anterior aspect of the left thigh. No facial or ocular symptoms of nerve trouble. No motor or sensory disturbances in the limbs, but the abdominal reflexes are feeble, and the cremasteric inconstant. Later there appeared areas of anæsthesia in the left foot, leg up to the knee, on the left side of the front of the chest, and on the left forehead and side of the nose, and the left side of the tongue and nasal cavity. Slight concentric lessening of field, but sight good, and free from colour or other disturbances. Intelligence average. Slight depression of spirits. Free from headaches or vertigo. Examination of kidneys, urethra, and bladder disclose nothing abnormal. The only troubles are frequency of desire to pass urine, polyuria, smallness of stream, and a slight vesical tenesmus accompanying the effort to urinate. He passes urine twenty or thirty times in the twenty-four hours. There is no sugar, albumen, bile, indican, blood or other abnormality in the urine, which is faintly acid, and has a specific gravity of 1007. Abadie points out that adult men are the usual subjects of the syndrome characterised above, that it is rare in women, and that alcoholism is generally present in male or female cases. Quantitative analysis of the urinary solids shows absence of phosphaturia, diminution of urea and nitrogen, and increase of the chlorides—all characteristic of hysterical polyuria according to Ehrhardt. By pollakiuria is meant the imperious necessity experienced for frequent micturition, a feature slightly marked in saccharine diabetes and Bright's disease, and more marked in vesical inflammations. In the first the frequency is a simple function of the polyuria. Abadie also thinks that a cerebral micturition centre exists which may be stimulated by visual and auditory stimuli, and instances such cases recorded by Pierre Janet (pollakiuria psychopathica). This patient was eventually fully cured of his trouble, and this is regarded as another point favouring its hysterical origin. It is also shown that polyuria and pollakiuria can be induced by hypnotic suggestion, and they then present the same characters as those of hysterical origin, as in the present case, and both are curable by direct or indirect suggestion.

(184) Catarrhal Affections of the Nose and Pharynx.

Wells (*Med. Record*, April 21st) emphasises the need for discovery of the constitutional causes underlying these conditions. The local trouble is generally of secondary nature when (1) there is no apparent adequate local cause, and local treatment has failed; (2) when the catarrhal inflammation follows a constitutional trouble, or when other catarrhal inflammations are present; (3) when the supposed cause is sufficient to produce the effects, and treatment of it relieves the catarrh. Herpes, urticaria, and pemphigus may appear as true reflexes of nasal origin, or act as a primary cause of nasal trouble. Dyspepsia often causes nasal catarrh, which is therefore relieved by nux vomica, pepsin, and hydrochloric acid, *post cibos*. Usually the nasal catarrh flatulence should be relieved, cardiac lesions examined for, and movable kidney, hysteria, and the gouty diathesis appropriately treated. When the latter state is obvious from the engorged baggy velum, fauces, and pharyngeal walls, pain in the larynx, difficulty in swallowing, and gouty deposits in the vocal cords, the general condition should be improved by salicylates, iodides, and alkalies, and 2 to 4 per cent. solution of thiol in glycerine applied locally. In hay fever constitutional treatment should always be adopted. Zinc phosph., $\frac{1}{12}$ gr.; quinine sulph., gr. ij; ext. belladon., $\frac{1}{8}$ gr.: one pill before each meal ought to be given in addition to the local treatment. In neurasthenia the glycero-phosphates are very efficacious.

(185) Chorea and Chorea Gravidarum.

Gilles de la Tourette (*Rev. Neurol.*, June 30th, 1900) opposes the view that chorea is associated with rheumatism. He states that of 17 consecutive cases of chorea at his clinic, only one had rheumatism before or during the attack, and that of several who returned after recovery none had shown any sign of the latter disease. He concludes that chorea has nothing to do with rheumatism, and that its diagnosis is entirely uninfluenced by the presence or absence of rheumatic manifestations. He maintains further that true Sydenham's chorea never comes on after puberty; he bases this statement on the fact that the two oldest of his patients, girls of 16 and 18 respectively, had never menstruated. From this he deduces the further view that chorea gravidarum is not the same as Sydenham's chorea; he holds that many cases so described are really examples of hysterical tremor, while others belong to the category of the convulsive tics, the pregnancy acting as the exciting cause. He admits that a few may be classed under the rare heading of chronic or Huntington's chorea. The author attaches great importance to the fact that in one of his cases the movements persisted after delivery. He believes that with the improvement of diagnosis along the lines he has indicated there will be no further need for the induction of premature labour in this affection.

SURGERY.

(186) The Surgical Treatment of Gastric Ulcer, with Hæmorrhage, but without Perforation.

Rodman (*Philadelph. Med. Journ.*, June 9th, 1900) discusses the treatment of the group of cases of gastric ulcer, not amenable to medical treatment in a reasonable time in which there is severe pain and uncontrollable vomiting. The operation of excision, having a mortality of 15 per cent., cannot be advised in all cases, but should be held in reserve for the more severe ones. If the ulcer is at the pylorus, or upon the anterior wall, [illegible] to [illegible], but if it be situated [illegible] and at the same time adjacent [illegible] frequently is, to adjacent [illegible] then gastro-enterostomy is preferable. The latter operation facilitates the healing of the ulcer by empty-

ing the stomach, permitting the ulcerated area being at rest, and by promptly relieving the hyperchlorhydria. If the ulcers are multiple, gastro-enterostomy should be preferred. When the element of shock is of grave import, then one of the quicker methods of gastro-enterostomy should be employed—for choice, that by the Murphy button. In regard to the hæmorrhagic cases it would be highly injudicious to perform laparotomy for the first hæmorrhage, and even when the surgeon sees the case the first time after the hæmorrhage has ceased and the patient is rallying from the shock. But when a case has bled freely once, has recovered, and then in a few days has bled seriously again, too great delay is hazardous, as the recorded cases show. In such conditions, pylorectomy, if the ulcer is at the pylorus, or gastrectomy for ulcers situated elsewhere, is the ideal operation. Both the hæmorrhage and the risk of perforation are cogent reasons for the complete operation should the conditions be favourable. If, then, the ulcer is at the pylorus, or on the anterior gastric wall, and reasonably free from adhesions, it should be removed. But if the bleeding point cannot be located the gastro-enterostomy, which cures the hæmorrhage on an entirely different principle, should be employed. It is especially successful in small and frequent hæmorrhages. Ligation of the bleeding vessel *in situ* is not to be recommended; the mucous membrane is so friable, it tears so easily, and bleeds so freely, that hæmorrhage is more likely to be increased than checked by any attempt to tie the open vessel. The other possible methods, except that of ligation *en masse* of the gastric mucous membrane, which is often desirable after an exploratory gastrotomy, suture of the ulcer, cauterisation, pyloroplasty, gastrorrhaphy, and curetting of the ulcer with or without cauterisation are not to be preferred to the methods advised, which have given a large number of favourable results.

(187) Treatment of Fractures of the Leg by Fixation Plates.

Steinbach (*Annals of Surgery*, April, 1900) states that in the open treatment of fracture of the leg, he has obtained good results from the application of a silver plate in the form of a cleat to the flat subcutaneous surface of the tibia secured by small galvanised steel screws. This method, he asserts, is simple in its execution, and, by maintaining the fragments in unyielding apposition, shortens the time required for bony union, and restores unimpaired function of the injured limb without shortening. The plate, which is designed to meet the indications of any fracture of the diaphysis of the tibia, is made of silver $\frac{1}{16}$ inch in thickness, $3\frac{1}{2}$ inches in length, and $\frac{3}{4}$ inch wide, with perforations for the screws $\frac{1}{2}$ inch apart, an incision slightly exceeding the length of the plate is made through the integument along the median line of the inner surface of the broken tibia, its centre corresponding to the line of fracture when the bone is broken in one place only, or to the centre of an additional fragment. After removal of small fragments of bone, blood clots, lacerated tissue, and other interposed or extraneous substances, the fragments are placed in position, the plate adjusted, and the drill applied through the perforations selected for the reception of screws. Two screws are usually employed at each end, and are secured by means of an ordinary screwdriver. Coexisting fracture of the fibula may in exceptional cases require attention, but, as a rule, such fracture adjusts itself fairly well when the tibia is properly set. The integument is united over the plate by sutures and the limb placed in a splint. The plate is permitted to remain in position until bony union has been effected. Its removal may then be accomplished with the aid of local anæsthesia alone.

(188) "Exothyropexy" in a Newly-born Infant.

Genevet (*Lyon Méd.*, October 29th, 1899) showed an infant 1 week old before the Soc. des Sciences Méd. de Lyon, who at birth was in a state of apparent death. After being resuscitated by energetic treatment there were great dyspnœa, noisy respiration, and retraction of the ribs. No nourishment could be taken. Pollosson discovered a tumour in the neck so small that it was not easily detected. It was uncertain whether it was the thymus gland, a hæmorrhage into a cyst of the thyroid, or a goître. A median incision was made, and a fairly large goître, which dipped deeply backwards, was found. The tumour was pulled outside the wound by gentle traction (exothyropexy), and the dyspnœa ceased at once and did not return. The hypertrophied lobe was left outside the wound without any dressing, as Pollosson preferred to await its atrophy, and later, if necessary, to hasten it by a few punctures of the thermo-cautery to excising it. The child's mother was goîtrous, and had lost a former child with similar symptoms.

(189) Congenital Diaphragmatic Hernia.

Funck-Brentano (*Bull. et Mém. Soc. Anat. de Paris*, No. 6 p. 537, June, 1900) describes the case of a female infant suffering from congenital diaphragmatic hernia. She was the result of the ninth pregnancy of a healthy woman who was forty years of age; two of the previous gestations had ended prematurely and four of them had been abortions. At the time of birth the infant seemed healthy, and during the first day of life expelled meconium and took the breast satisfactorily. On the second morning, however, it took convulsions, became cyanotic on several occasions, and died when 55 hours old. A radiograph was made of the cadaver and compared with that of a normal infant of the same age, and it was at once evident that the left side of the thorax contained a large packet of the intestines. On making a necropsy it was found that in the abdominal cavity were the genito-urinary organs, the liver, stomach, pancreas, and the terminal part of the large intestine. Posteriorly and on the left side there was a free communication between the abdominal and thoracic cavities; and in the left pleural sac were the small and large intestines and near to them the spleen, which was enlarged and deeply furrowed in an irregular manner. The left lung was discovered at the top of the thoracic cavity and consisted of two lobes which, together, were no larger than a bean. The heart was entirely displaced to the right of the middle line, as were also the great vessels, but they passed by the usual openings through the diaphragm. The right lung contained air, but was displaced upwards and backwards. There were no other malformations.

MIDWIFERY AND DISEASES OF WOMEN.

(190) Torsion of Pedicle of Pedunculated Fibroid.

Schwarz (*Comptes Rendus de la Soc. d'Obstét. de Paris*, May, 1900) reports a case of a relatively rare condition compared with torsion of the ovarian pedicle. The patient was a nullipara, aged 48, regular and free from metrorrhagia. In July, 1899, she suffered from severe general peritonitis; the symptoms lasted for six weeks. During convalescence a hard fixed tumour was detected in the hypogastrium and left flank, mounting to the false ribs. In the middle of April Schwarz saw her and diagnosed torsion of the pedicle of a fibroid, as he had observed a similar case three years before, and there was evidence of torsion of a pedunculated tumour which was clearly connected with the uterus. He operated and found the tumour adherent to the parietes, intestine, and omentum. On separation of the adhesions the tumour appeared like a large kidney, about 4 inches long by nearly 8 broad. It was connected with the right cornu of the uterus by a pedicle only $\frac{3}{4}$ inch long and as thick as a stout pencil. It was twisted one turn and a-half. The tumour was removed, the pedicle being ligatured. As a myoma lay in the posterior wall of the uterus and the patient was 48, Schwarz removed the appendages. The pelvis was drained on account of oozing. The patient recovered.

(191) Vaginal Hysterectomy for Cancer.

Howard Kelly (*Bull. of Johns Hopkins Hosp.*, March, 1900) now considers that as ordinary uterine cancer extends progressively through the tissues from the cervix, whilst glandular metastases are very late, the aim must be to clear away as much of the cervix as can be done rather than to run needless risks in extirpating the pelvic glands. The ureters must be first catheterised, the diseased area scraped, and the vagina stripped up quite one inch around the area of infection. The peritoneum is opened on both sides; if necessary, a piece of the base of the bladder is excised. The uterus is now only held in by the broad ligaments. The fundus is drawn down and the uterus bisected vertically. Then one half of the body is severed from

within outwards, from the corresponding half of the cervix, the uterine vessels, round ligament and uterine cornu clamped. The remaining half is treated in the same way. Ligatures are now placed where the clamps were applied. The ovaries and tubes are next removed; as there is no uterine body in the way, this stage of the operation is easy. The last stage but one of the special part of Kelly's new procedure is the removal of that half of the cervix which appears the least diseased. As much of the tissue around it is cleared as is possible, the rigid catheterised ureter must be kept under all the time during the enucleation. There is now plenty of space for removing the more involved side of the cervix. Skene's cautery-clamp or Mackenrodt's igni-exterpation may be used at this stage. If the ureter be free and beyond the diseased area it may be dissected out and left intact. If otherwise, the operator must not hesitate to cut it off above the diseased area, proceeding with the wide enucleation of the nodule as if the ureter did not exist. After the enucleation, the ureter may then be turned into the denuded bladder and stitched there. In conclusion, the anterior and posterior peritoneal surfaces are drawn down and attached to the vagina and are again sutured together in the middle line, so as to leave but two small openings up into the pelvis which are loosely stuffed with gauze. Kelly has operated on nine cases after this method, which allows of a freedom of manipulation at the most important stage which no other method can afford. Hence more tissue around the limits of the cancer can be removed, so that there must be a high percentage of permanent recoveries.

---

(192) Breech Presentations: Value of Prophylaxis.

De Monchy (*Nederland. Tijdschrift van Geneeskunde*, No. 5, 1900) places a low value on manipulation for the conversion of breech into head presentations, and objects to it being taught to midwives. In the Leyden extern practice, 100 breech cases occurred in the ten years ending last autumn. The students are of necessity not highly experienced, and the resident assistant obstetrician is changed almost yearly. Nevertheless, 93 children were born alive, 42 without help from the assistant, 7 were delivered asphyxiated or dead, including, it must be noted, 1 case of placenta prævia; only 3, it appears, were lost. Out of the 93 cases, 18 were in primiparæ, whilst out of the 3 cases where the child was dead 2 occurred in primiparæ. During the same period, 25 breech cases were delivered in the Leyden Maternity; 20 children were saved, 11 of these cases being in primiparæ; 5 children were born dead; in 2 the labour was premature and the pelvis narrow; in 2 there was placenta prævia, in 1 congenital malformation of the child. In many of the above successful cases labour was so quick that the student had hardly time to manipulate. Not a single child was lost when the resident assistant was present. Prophylactic turning, then, is of questionable value, so well do most breech cases fare if not interfered with too much. Explorations weekly or fortnightly during the later stages of labour worry the patient. Midwives are now as ever too fond of counting breech presentation as pathological, and therefore too ready to interfere.

---

(193) Placenta Prævia: Air in Veins.

Hubl (*Wien. klin. Woch.*, February 1st, 1900) reports two deaths in placenta prævia cases, from the entrance of air into the veins. The first patient was a rachitic woman, aged 40. She had borne five children. There was very severe flooding; the tampon was applied for forty-eight hours, and then version was performed under an anæsthetic. Little blood was lost during the latter manœuvre, yet the patient died suddenly. The left ventricle was found contracted; the right ventricle and pulmonary artery were resonant on percussion, and distended with air. In the second case there was no necropsy. The patient was delivered, then became cyanosed, suffered from severe dyspnœa, and died fourteen hours after delivery. The cardiac area was increased, but was resonant on percussion, and bubbling sounds were heard on auscultation.

---

(194) Tertiary Syphilis appearing in Pregnancy.

Marschner (*Centralbl. f. Gynäk.*, No. 27, 1900) publishes notes of a woman, aged 27, who, after two normal pregnancies, miscarried four times. At the beginning of her seventh pregnancy she was treated carefully with potassium iodide, though no symptom of syphilis had apparently been noted beyond the suspicious miscarriages. At the fourth month, notwithstanding all care in treatment, specific ulcers appeared on the perineum and labia. Within a week the integuments of the perineum and the mucous membrane of the vulva and vagina were completely destroyed. During this process the patient was taking tannic oxide of mercury by the mouth. The ulceration was stopped by local application of mercury dissolved in fuming nitric acid and large doses of potassium iodide. Abortion, however, followed. Six months later a fresh attack of ulceration occurred, finally cured, after much trouble, by Zittmann's decoction.

THERAPEUTICS.

(195) The Treatment of Hay Fever by Immunisation.

Holbrook Curtis (*New York Medical News*, July 7th, 1900) conceived the idea that immunisation against hay fever and other forms of rhinitis and coryza might be attained by hypodermic injections of weak extracts of the plants or flowers found most prone to induce attacks of hay fever. The idea was suggested by observing that two girls who were susceptible to coryza from inhalation of ipecacuanha powder could acquire a temporary tolerance for the drug by taking internally small doses of the tincture or syrup of ipecacuanha for a few days. Having been consulted by a lady patient who suffered from coryza and severe sneezing whenever she passed a florist's shop, Curtis prepared aqueous extracts of flowers which he administered to her hypodermically with the hope of establishing immunity. This was first tried with an extract of roses with the result that tolerance was acquired and immunisation established. Then various other extracts of flowers were prepared and similarly administered, until the lady acquired a complete tolerance for flowers, and could enter a florist's shop without suffering any distress or inconvenience. As hay fever was traceable in several instances to the action of ragweed, golden-rod, and lily of the valley, preparations of these flowers were made and administered hypodermically to patients who were found to have contracted hay fever from the smells and odours of these plants. In the case of ragweed gratifying results were obtained, and Curtis states his belief that many varieties of hay fever seen by him were cases of ragweed coryza-asthma, and that they were cured by the treatment adopted. He urges the importance of further work and observation in the direction of treating hay fever and other forms of rhinitis and coryza on the principles above mentioned, so that the true value of the method may be ascertained.

---

(196) The Significance of Iodinophile Leucocytes in Diseases of the Blood.

Hofbauer (*Centralbl. f. inn. Med.*, February 10th, 1900) has sought for Ehrlich's iodine reaction in the leucocytes in certain anæmic conditions in man. Czerny, in 1893, showed that Ehrlich's reaction, which consists in the granules of certain leucocytes being stained brown by iodine, was obtained in some anæmic conditions in dogs, though not normally present in them. The staining fluid used by the writer consists of iodine 1 gram, potassium iodide 3 grams, and water 100 c.cm. to which enough gum arabic is added to produce the consistency of syrup. An excess of this is placed on a slide, the dried film of blood on the cover slip is allowed to swim on its surface for one minute, and the excess of the iodine solution is removed from the edge of the cover slip as completely as possible by blotting paper. The preparation is then ready for examination. Hofbauer's investigations show that, broadly speaking, iodinophile leucocytes are found only in pernicious anæmia, in severe anæmia secondary to serious diseases, and in leukæmia, that is, in cases where the prognosis is bad. The presence or absence of the iodinophile cells does not, however, necessarily indicate respectively bad or good prognosis, since cases where the cells are found may recover, and cases where none are found may end fatally. Thus, iodinophile cells may be absent in the early

stage of pernicious anæmia and in pseudo-leukæmia. Goldberger and Weiss concluded that the intracellular iodine reaction, even when present in a small number of leucocytes only, pointed to the presence of some active suppurative process. They added that this conclusion was not justified if pneumonic processes were present. The writer's researches show that it is not sufficient to exclude pneumonia before diagnosing suppuration from the iodine reaction, since it may be present quite apart from coexisting suppuration in certain blood diseases. The statement of Kaminer that the iodine reaction is never found except in cases of marked leucocytosis is not correct, since the writer found it in cases of pernicious anæmia and severe anæmia where the quantity of leucocytes was diminished.

(197) Treatment of Eczema in Children.

Rille (*Wien. klin. Rund.*, March 18th and 25th, 1900) thinks that tar preparations are contraindicated in children, and that milder applications should be used. For intertrigo he recommends talc as being less liable to form lumps than the vegetable dusting powders such as starch and lycopodium. When the genitals are affected he uses carron oil or lead lotion. In severe cases a 0·05 per cent. solution of sublimate lotion is employed. He is of opinion that ointments aggravate acute eczemas, and recommends a lotion of boric acid, menthol, and carbolic acid (1 per cent.) in spiritus vini Gallici. In moist eczemas with crusts, after removal of the latter, he applies compresses of silver nitrate (1 in 400) twice daily for two hours, and in the intervals diachylon ointment. Cases of universal eczema are treated in bed, vaseline being applied several times a day, and the inside of the night dress dusted with starch.

(198) The Best Method of Administering Diphtheria Antitoxin.

Musser (*University Med. Mag.*, March, 1900) prefers to give antidiphtheria serum in small and, if necessary, repeated doses, rather than to employ the large initial dose usually recommended. For children below 8 years he gives at first only 500 immunising units, to be repeated at intervals of six hours if the temperature does not fall, or if the local or general symptoms become worse. For children over 8 years he gives 1,000 units, and repeats the dose every 8 or 12 hours, as needed. He claims to have secured results as good as any recorded, and to have had fewer cases of urticaria and general reaction than is usual after large initial doses. The only disadvantage is the pain caused by successive injections, but this does not outweigh the advantages.

(199) Case of Psoriasis cured by Thyroid Extract.

Petrini (*Bull. de l'Acad. de Méd.*, February 20th, 1900) reports a case of general psoriasis cured by thyroid extract alone, the patient having no local treatment. In the course of a few months the patient took 543 capsules, each containing 0·10 centigramme of thyroid extract. No symptoms of thyroidism occurred.

(200) The Influence of Light on Morbid Processes.

Boeder (*Arbeit a. d. Kaiserl. Gesundh.*, vol. xvii, pt. 1) has carried out certain experiments on the therapeutic value of electric light, with results mainly negative, and in some respects unfavourable. The results of other authors have differed widely. He experimented on guinea-pigs, rabbits, mice and rats infected with anthrax, cholera, tubercle, and other bacterial poisons. By attenuating cultures he was able to study the effect of the light on subacute and chronic as well as on acute processes. He summarises his results as follows: The electric rays, both incandescent and arc, have a direct bactericidal power. This, however, has no appreciable effect on general infective processes, acute, subacute, or chronic. Localised disease processes, where bacteria are present either in or under the skin, are favourably affected by the arc light, that is to say, some bactericidal action is to be observed. Exposure to the light stimulates cell activity and increases the vascularity of a part, and in this way acts favourably on the morbid processes. It is only in chronic infective processes that the light-baths are likely to be used with advantage, and perhaps exclusively in those where the process is cutaneous or subcutaneous.

PATHOLOGY.

(201) Variability in Epileptic Reactions to Toxic Agents.

Joffroy and Servaux (*Revue Neurolog.*, March, 1900) communicated to the Société de Neurologie of Paris the following results obtained from an extensive series of experiments on various animals to determine the toxicity of various substances. Observing that absinthe, even in small doses, has a rapid tendency to produce epilepsy, while in large doses it produces grave cerebral troubles in animals, the authors note that in man there is a hereditary predisposition to act differently for different poisons. This predisposition (or variability) of individuals is found also in animals. Thus: (1) In the case of 113 rabbits subjected to the action of ethyl-alcohol, 1 had epilepsy, 4 had non-epileptic general convulsions, and 83 had localised convulsions, and the others non-convulsive troubles; for the same poison in 33 dogs, 1 had epilepsy major, 2 had non-epileptic localised convulsions, and 29 had non-convulsive troubles; (2) For the study of furfurol, 85 rabbits were used; 19 had epilepsy major, 18 had non-epileptic general convulsions, 25 had localised convulsions, and 23 had non-convulsive troubles; (3) the action of aldehyde on 58 rabbits gave 8 cases of major epilepsy, 9 of non-epileptic generalised convulsions, 22 localised convulsions, and 19 non-convulsive accidents; (4) for absinthe given gradually and in small doses to a lethal degree in 10 rabbits, 1 had major epilepsy, 2 had non-epileptic general convulsions, 4 had localised convulsions, and 3 died without convulsions; (5) for morphine in 38 rabbits, 11 had major epilepsy, 9 had general convulsions without epilepsy, 10 had localised convulsions, and 8 non-convulsive accidents; (6) with urine in the case of 42 rabbits, 3 had major epilepsy, 8 had localised convulsions, and 31 had no convulsions; (7) in all cases the lethal dose was sensibly constant, even when the individual reactions varied.

(202) Parasitic Bodies in Vaccinia Vesicles.

Siegel (*Centralbl. f. Bakt.*, August 22nd) describes the bodies found in the vesicles of vaccinia, and in the young vesicles of foot and mouth disease which he considers parasitic in nature. There are three forms: (*a*) a large cyst form with double contour, dark brown in colour, and from 10 to 18 micros in diameter; (*b*) smaller form brighter in colour, and from 6 to 8 micros in diameter; (*c*) a minute form which is usually found collected into groups. Between these three there is a genetic connection; they are all very resistent to stains and chemical reagents, especially the small forms in groups, and Siegel has not been able to discover a satisfactory method of staining. He considers them coccidia. The cyst forms contain spores, but the young forms multiply by simple division. Siegel considers that these researches may have an important bearing on immunity. In all the acute exanthemata there is a period of immunity of greater or less duration; it may be supposed that during this time sporocyst forms are still present in the individual, and that until they are destroyed a new infection is impossible. The organisms were not cultivated, and do not grow on ordinary media.

(203) The Tubercle Bacillus in the Milk of a Tuberculous Mother.

Roger and Garnier (*Compt. Rend. de la Soc. de Biolog.*, 1900, p. 175) report the case of a mother, aged 34, with acute tuberculosis and a large cavity in the upper lobe of the left lung, in whose milk the tubercle bacillus was found to be present. A guinea-pig inoculated with the milk died five weeks later with general tuberculous lesions. The child of the patient was suckled from the third to the sixth day after birth, and after that fed by the bottle; it died at the sixth week, and *post-mortem* examination showed tuberculous foci in the mesenteric glands, liver, spleen, and kidneys, in which the bacillus was demonstrated microscopically. The affection of the mesenteric glands points to the probability of infection being intestinal. Clinically the breasts of the mother were quite healthy, which shows that absence of tuberculous disease of the udder is no guarantee that cow's milk does not contain the bacillus. Cattle, therefore, which show no reaction in the udder to tuberculin may still convey the infection if there are tuberculous lesions elsewhere.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(204) The Etiology of Exophthalmic Goitre.

Breuer (*Wien. klin. Rundschau*, 25, June 24th, 1900) records some observations which are likely to throw new light upon the causation of exophthalmic goitre. Speaking generally, two views are held with regard to the etiology of the malady: Some regard it as due entirely to an alteration in the secretion and the normal physiological activity of the thyroid gland, and denote this morbid condition by the term of "hyperthyroidism;" while others hold that there occurs coincidently with this alteration in the normal function of the thyroid gland a pronounced change in the central nervous system, and that this latter condition is not a mere accident, but plays, indeed, a highly important part in the production of the affection in question; hence they suggest the name—as a matter of simplification of the nomenclature, as they call it—"neuro-cardiac disease," as expressive both of the pathology and the striking clinical phenomena. The first of these views has, in the very first instance, received most of its support from German and English pathologists, and especially from Moebius in Germany and Greenfield (Bradshaw Lecture, 1893) in this country; of late years, however, this view has been adopted, though modified to some extent, by far the greater number of all the writers on this subject. Breuer, in this paper, endeavours to show that, if this view be applicable, it could be only applied to a limited number of cases, while in the remainder the etiology varies individually. Thus, he reports the case of a man, whose previous general condition showed no morbid signs, in whom he was able to observe the development of the well-known triad of clinical symptoms in connection with a sudden formation of an inflammatory abscess in the thyroid gland; and in another group of cases (10) all the typical signs of exophthalmic goitre followed upon and were evidently, according to the author, produced by the external application of a strong solution of iodine to the thyroid gland. This observation forms a valuable contribution to our knowledge of the etiology of exophthalmic goitre; indeed, it clearly shows that exophthalmic goitre, both in an acute and chronic form, may arise under conditions which are by no means favourable to the so called thyriogenic theory, which—possibly in the absence of better knowledge—has now obtained the favour of most clinicians. Moreover, the cases published in support of the latter view, in which thyroid extract given in excess—nay, even a single overdose, as in the famous case reported by Beclère—produced symptoms (great prostration, followed by sweating, distressing headache, tachycardia, tremor) not unlike those of Basedow's disease, do not stand a close examination with regard to their actual relation to that affection. Hence the conclusion may be rightly drawn: (1) That the question with reference to the genesis of exophthalmic goitre is far from being settled; (2) that in all probability there is a combination of diverse etiological factors, varying, of course, in degree and extent in different individuals, which act together in producing the disease under consideration.

(205) The Remote Prognosis of Sero-fibrinous Pleurisy.

Salanoue-Ipin has endeavoured to ascertain by means of statistics some information concerning the important question of prognosis in pleurisy (*Arch. de Méd. Navale*, No. 4, 1900). It has been stated that all cases of pleurisy are tuberculous unless proved to be otherwise, and consequently pleurisy *a frigore* does not in the opinion of some exist. The investigations of Kelsch Vaillard and others appear to support the conclusion that the vast majority, if not all, of cases of pleurisy not appearing in the course of some definite disease result from an invasion of the pleura by tubercule. Dieulafoy, Netter, Débove and Achard, on the other hand, believe that there are many cases of a simple primary pleurisy which are non-tuberculous. The importance of Salanoue-Ipin's observations is that they have been collected under the same circumstances, namely, sailors in the French navy. All cases manifestly tuberculous were eliminated as well as pyæmic or other forms of pleurisy having a definite history. The writer collected 352 cases of primary sero-fibrinous pleurisy. Thirty-two died during the course of the attack, and of the remaining 320, 131 died after leaving hospital. Of these 84 showed definite tuberculous affection, in 19 the cause of death was unknown; in 13 it was independent of tubercle, and 15 lost their lives at sea. Thus, the enormous proportion of tubercle is striking, and very probably the 19 cases of which the cause of death could not be ascertained included other cases of tubercle. As a rule, tubercle seems to appear very shortly after the outbreak of pleurisy, while if several years have passed it becomes much less common. Another interesting point emphasised by the writer is the high proportion of cases of tubercle among those leading a seagoing life. The idea that such persons are likely to escape tubercle is fallacious. They are exposed to considerable changes of temperature, and for many hours at a time are shut up in close confined spaces.

(206) Fibrinous Bronchitis.

Cesaris-Demel (*Giorn. dell' Accad. di Med. di Torin.*, July, 1900) publishes a case of fibrinous bronchitis (fatal) in a man, aged 50, due to pressure on the left bronchus from a large aneurysm of lower part of the aortic arch. The left lung was completely atelectic. There was no evidence of previous bronchitis. Pressure on the bronchial vessels doubtless led to separation and death of the pulmonary epithelium, which acted as a fibrin ferment on the plasma, and so produced the fibrinous clot, which measured 10½ cm. in its greatest length. The case adds a further possible symptom to the number of those already known in aortic aneurysm, and shows that pressure may be a cause of fibrinous bronchitis.

(207) The Plantar Reflex in the Newborn Infant.

Gaetano Finizio (*Pediatria*, vlii, 254, August, 1900) draws certain conclusions from the study of the plantar reflex in over 500 newborn infants in the Maternity at Naples. He notes the difficulties of exact observation of this reflex in young infants, and points out that it is necessary to elicit it when the muscles of the leg and foot are relaxed; further, he has found that in the same newborn infant tickling the sole will cause flexion of the toes, while pricking will produce extension, so that in order to get reliable results the same degree of cutaneous excitation must be employed. In 5 per cent. of the cases (infants from 1 to 3 days old), the plantar reflex was absent: in 10 per cent. it was indefinite; in 15 per cent. it produced extension of the great toe alone or of all the toes; and in 70 per cent. it caused flexion of the toes. It may therefore be concluded that in the great majority of newborn infants the plantar reflex shows itself in flexion of the digits. The cases in which there was digital extension were generally those in which the birth had been abnormal—for example, delayed labour, forceps application, face presentation, etc.; in two instances in which forceps had been used there was flexion of the toes on one side, and extension on the other. The plantar reflex is one of the most constant of all the skin reflexes: on the other hand, the cremasteric reflex is only met with in 2 per cent. of newborn infants: the patellar reflex, like the plantar, is present in 70 per cent. of the cases. When extension of the toes is met with, the other cutaneous and tendon reflexes are often well marked and active.

SURGERY.

(208) Non-Congenital Urinary Pouch in the Male.

Pouly (*Lyon Médical*, February 4th, 1900) relates a case of rare type in the practice of Rollet of Lyons. The patient was a man aged 64. He had never contracted gonorrhœa, but his urethra was ruptured by a blow in the perineum when he was 35 years old. For twenty years after the accident he suffered badly from stricture; then he underwent internal urethrotomy. Three years before admission into hospital

suprapubic lithotomy was performed, and three large calculi removed from the bladder. A year later the patient broke a catheter during use, external lithotomy was performed, and the end of the instrument, 2 inches in length, extracted. Then, about twelve months later, he noticed that during micturition a small tumour formed under the root of the penis, immediately in front of the scrotum. It increased steadily as the bladder emptied, and then went down just as regularly when the urine ran out of the meatus at the end of micturition. It was perfectly transparent, fluctuating, free from tenderness, and from any evidence or history of inflammation. It was not adherent to the skin, which was not red. Urine coming from the meatus in a stream at the beginning of micturition was first collected. Then the patient pressed the pouch, as he was always obliged to do under the circumstances, and it emptied; the urine collected was then found identical with the first sample. The prostate was enlarged. Full-sized catheters could be passed into the bladder, meeting with no resistance, except at the prostate. In retracting the catheter the end could be manœuvred into the pouch. The patient bore signs of chronic urinary poisoning. Rollet made an incision over the pouch. The cavity was clearly formed by a dilatation of the floor of the urethra, a little under 2 inches in the long axis. The tissues involved in the pouch were quite healthy; they were partially incised; then a No. 15 Nélaton's catheter was introduced, and the canal closed with three layers of suture. The patient's urine, it was already known, contained pus. On the tenth day uræmic symptoms set in and death followed within 24 hours. Both kidneys were suppurating, especially the left. Only 6 cases of non-congenital urinary pouch are recorded. They include three varieties: (1) Dilatation of urethra above an impacted calculus (Petit, 1; Voillemier, 2 cases); (2) dilatation of urethra after its rupture immediately above an impacted calculus (Paoli, 1 case); (3) dilatation of urethra apparently developed behind a stricture after chronic gonorrhœa (Chopart, 1 case); and (4) dilatation of urethra, following hæmatoma of perineum (Chopart, 1 case, in a postillion).

(209) Operative Treatment of Arterio-Venous Aneurysm.

STIMSON (*Annals of Surgery*, June, 1900) has recently brought under the notice of the New York Surgical Society a case of arterio-venous aneurysm of the femoral vessels from gunshot wound, in which he tied the femoral artery above and below the seat of communication between this vessel and the vein. The patient made a good recovery, and was discharged cured during the second week after the operation. In referring to the usual treatment of such cases by the application of the double ligature to both vein and artery, and extirpation of the sac, Stimson said that though he could conceive of cases where such a procedure would be preferable to simple double ligature, he held that an operation which did not interfere with the vein was less likely to cause subsequent trouble. By double ligation of the artery alone there is less interference with the circulation, and the danger of gangrene is diminished. In replying to some criticism made by Curtis, who is an advocate of the more radical operation, Stimson, whilst acknowledging that a recurrence is not unlikely to follow simple double ligation of the artery, pointed out that simultaneous ligation of the vein is a serious and sometimes a very bloody operation.

(210) Bladder Symptoms in Appendicitis.

DURET publishes a paper (*Sci. Méd. de Lille* 1900, and *Journ. de Méd.*, April 25th, 1900) in which he states the correlation which may exist between appendicitis and vesical symptoms. In the first place the vermiform appendix may be in actual contact with the bladder, and lesions of the former may therefore react upon the latter and produce a series of symptoms which are partly reflex, but in more severe cases may be due to actual involvement of the bladder itself. Thus retention, vesical tenesmus, dysuria, and frequency of micturition are recognised symptoms, but there may be a series of suppurative conditions as paravesicular abscess, vesical fistulæ in different forms, including salpingo-vesical, intestinal vesical, etc., all of which are accompanied by more or less severe cystitis and pyocystitis. Lastly, calculus may be due to appendicitis by adhesion between the two forms and the establishment of a fistula. These latter are, however, so extremely rare that the author considers it only necessary to mention them.

(211) Malignant Œdema of Eyelids.

THOINOT AND GIROT (*Progrès Médical*, January 20th, 1900) reports a case of this disease in a shepherd; it was due to a sting from an insect. There were cases of malignant pustule amidst flocks of sheep in the neighbourhood. The patient appeared to be dying, but on the application of compresses steeped in sublimate he rapidly improved and ultimately recovered.

(212) Congenital Lateral Ventral Hernia.

SCHENK (*Prag. med. Woch.*, No. 1, 1900) noted this rare condition in an infant which presented at the breech and was safely delivered. A swelling of the size of a walnut was observed on the right side, between the ribs and the crest of the ilium. It greatly increased when the infant cried, but was easily reduced when it was quiet. This hernia was found to slip through a hernial neck about two fifths of an inch in diameter. The finger passed through the neck could easily detect the edge of the liver Wyss declared that the hernia was of the lateral anterior ventral variety. There was no distinct evidence of congenital defect at the seat of the hernia or elsewhere. Yet it seemed most probable that the muscles on the right side of the abdomen were ill-developed owing to sharp pressure of the strongly-flexed right knee against the loin; when Schenck flexed the knee he found that it fitted into the gap in the muscles which formed the neck of the sac. This forced flexion of the knee in the fœtus is due to scantiness of liquor amnii in early pregnancy. A pad held on with strapping was applied to compress the sac.

MIDWIFERY AND DISEASES OF WOMEN.

(213) Mesenteric Cyst.

SCHRAMM (*Berl. klin. Woch.*, December 25th, 1899) operated on a woman, aged 48, free from any history of disease or injury until two years previously, when digestive troubles, constipation (very severe), abdominal swelling, and dyspnœa were noticed. Schramm found the abdomen extremely swollen, and tympanitic. On careful palpation a tumour of the size of an adult head was detected. It fluctuated, and was dull on percussion. There was resonance in both flanks. On vaginal exploration the tumour was found to be separate from the uterus. Ovarian cyst was diagnosed, and it happened that a tumour of this kind, as large as an orange, was discovered at the operation, where a median incision was made below the umbilicus, and a very thin-walled cyst, the chief cause of the enlargement, was then seen to lie between the folds of the mesentery. It was enucleated without much difficulty, and held over 13 pints of a watery fluid. The redundant mesenteric flaps were resected, and some vessels ligatured. The cyst wall was fibrous, and lined internally with a layer of endothelial cells. Schramm considers that this tumour was a cystic dilatation of the mesenteric chyle ducts. The ovarian cyst was also removed; the patient did very well.

(214) Retention of Dead Fœtus to Term.

BELLY (*Rev. Mens. de Gynéc., Obstet., et Pædiat. de Bordeaux*, June, 1900) reports a case where the fœtus died about the fourth month and was retained to term. The patient was 38, and had been married for eleven years; she had miscarried three times and borne two children to term. The last period was seen at the end of July, 1899. All the signs of pregnancy developed and proceeded normally till the end of November, when the patient received a shock. After that date she ceased to increase in size; indeed the abdomen soon began to grow less and less. The appetite and strength distinctly improved. The cervix was hardly if at all softened. The uterus seemed to be retroverted by a firm tumour, which felt more like a fibroid than a gravid uterine body. A case had recently been observed where amenorrhœa for five months and escape of colostrum-like fluid from the breasts had naturally given rise to suspicion of pregnancy, but at the operation the tumour was found to be a uterine fibroid with no fœtus in the uterine

cavity. On the 8th of May natural labour pains set in and Belly's patient was delivered of a fleshy mass weighing over three-quarters of a pound. It was firm, and whitish, the membranes were thickened and intact, the placenta was shrivelled and clearly had been for long detached from the uterus. On opening the membranes a thick dust-coloured fluid escaped and the fœtus appeared. It was covered with calcareous deposit which had almost obliterated the cranial sutures and made the limbs and even the cord rigid and brittle. In short, mummification had set in. In Vivie's recent case of retained fœtus septic symptoms set in; in Belly's case there was no evidence of sepsis. Fieux, in a discussion on Belly's case, referred to the death of the fœtus at the fifth month by twisting of the cord round the arm (*sic*). It was delivered four months later, just at term. Vivie believed that sepsis might occur even when the membranes remained intact. In long retention of a fœtus the cervix undergoes a characteristic toughening, quite unlike the toughness of that part of the uterus when gravidity does not exist.

(215) Echinococci Simulating Ovarian Dermoid.

STERNBERG (*Centralbl. f. Gynäk.*, No. 29, 1900) reports a case under the care of Gersuny, of Vienna. The patient was a girl, aged 20, who had noticed a tumour below the umbilicus to the right for two years; it grew steadily larger, and dull pains set in in the right hypochondrium. The tumour was very smooth and round, and fluctuated distinctly; its mobility was very marked. It seemed to be a dermoid of the right ovary. In Douglas's pouch lay a fixed, fluctuating tumour; its convexity rose high above the pelvic brim. Another tuberous mass lay in the left loin; it was movable, and seemed attached by a pedicle to the loin as far back as the left kidney, which could be easily defined. Abdominal section was performed. The right ovary was found stretched over the tumour, which lay to the right below the umbilicus. The tumour was enucleated from the broad ligament, and the incision with the remains of the ovary sewn together. The mass in Douglas's pouch was much more difficult to enucleate; the left ovary was stretched over its capsule, as on the right side. Then it became clear that the tumours were hydatid. The omentum was infested with echinococcus cysts of varied sizes; small cysts lay in the mesentery of the vermiform appendix. Two large cysts occupied the right lobe of the liver; they showed signs of old suppuration, and were no doubt the starting point of the disease. The mesenteric cysts were enucleated. One of the cysts in the liver was opened, then iodoform-glycerine emulsion poured in, and the cyst closed. The patient made a good recovery; prognosis is doubtful, as there may be cysts remaining in other organs. The ovary is rarely involved in hydatid disease.

(216) Hæmorrhage at Eighth Month; Rupture of Sinus Circularis.

DEMELIN AND GADAUD (*L'Obstétrique*, July 15th, 1900) report that a primipara, aged 31, was attacked with uterine hæmorrhage and sharp abdominal pain when advanced seven and three-quarter months in pregnancy. Next day the flooding ceased. The fœtal movements stopped on the day of hæmorrhage, March 12th. On the 17th the uterus was felt to be smaller; the fœtal heart had ceased to beat. The inferior segment was very thin. Rupture of the circular sinus was diagnosed by exclusion; there was no evidence of detachment of the placenta or of placenta prævia. On March 18th a macerated fœtus was expelled spontaneously; there was no trouble with the placenta. Recovery was rapid. There was a mass of clot close to the border of the placenta which compressed its cotyledons; from the clot dark-brown vascular tracts ran on each side to the circumference of the placenta, but at the point where the clot touched the placenta no trace of the circular sinus existed.

THERAPEUTICS.

(217) The Dangers of Hypodermic Injections of Gelatine.

FREUDWEILER (*Centralb. f. inn. Med.*, July 7th, 1900) considers that any conclusions as to the real value of hypodermic injections of gelatine as a hæmostatic are premature. It is certain, however, that the injections are not so harmless as has been generally stated, and that they have been followed by the appearance of boils, and by the production of thrombi in undesirable positions, such as the carotid arteries. One of Barth's patients died in convulsions shortly after an injection. The writer now reports two cases where the gelatine certainly aggravated the disease for which it was given, namely, hæmorrhagic nephritis. (1) A girl, aged 15, had had acute nephritis when 7 years old, from which she was said to have recovered completely. In May, 1899, the present illness began, the legs became œdematous, and the cardiac apex was found in the nipple line. The quantity of urine amounted to 21 or 28 ozs. daily, the specific gravity was 1012 to 1015, and there was from 1½ to 3 per mille albumen and a quantity of blood. As the condition did not improve 7 ozs. of a solution consisting of 1 gram of gelatine, 2 grams of glycerine and 100 c.cm. of water were injected under the skin of the thigh on both January 4th and January 6th. On January 6th and 7th the urine became smoky and contained numerous red corpuscles and a quantity of brown detritus. In the filtered urine methæmoglobin was present. Besides the increase in the hæmaturia and the addition of hæmoglobinuria the quantity of albumen steadily rose till it reached 9 per mille on January 18th. Though the hæmaturia and the hæmoglobinuria gradually disappeared, the quantity of albumen remained permanently double as much as it was before the injections. (2) A woman, aged 27 years, had acute hæmorrhagic nephritis after the puerperium. The renal hæmorrhage continued, and an injection of 10½ ozs. of a solution consisting of two grams of gelatine and 100 c.cm. of sterilised normal saline solution was given. The immediate result was, as in the first case, an intense hæmaturia and hæmoglobinuria with an increase in the albuminuria, but 8 days later the urine had returned to the condition in which it was before the injection, and no permanent damage resulted. These cases show that diseased kidneys are an absolute contraindication to the employment of gelatine as a hæmostatic. In this connection a case of Bauermeister is instructive: 15 c.cm. of a 1 in 15 gelatine solution were injected hypodermically 3 times a day for severe metrorrhagia in a woman with chronic parenchymatous nephritis. On the second day there was headache, and the patient rapidly succumbed with typical symptoms of uræmia. It is possible also that Barth's patient died of uræmia.

(218) Digitalis, Digitalin, and Digitoxin.

ARNOLD AND WOOD (*Amer. Journ. Med. Sci.*, August, 1900) have investigated the question whether any of the proximate principles found in digitalis represent the therapeutic activity of the crude drug. They avoid as useless any discussion as to the chemical relations of the various bodies which each in turn have been claimed by different investigators as the active principle of digitalis, and confine themselves to an examination of the comparative value of the tincture of digitalis of "digitalinum germanicum" (Merck's digitalin), which is readily soluble in water, and of digitoxin (Merck's). The experiments were made on dogs, and the drugs were injected intravenously. They conclude that both digitalin and digitoxin produce the full effects of digitalis on the circulation. (1) All three drugs stimulate the cardio-inhibitory mechanism both centrally and peripherally. The slowing of the heart is prevented or abolished by the injection of atropine, and is not wholly prevented by cutting the vagi. This shows that the stimulation of the cardio-inhibitory mechanism is limited chiefly to the peripheral part of the apparatus, though since the heart beats may increase in frequency on section of the vagi after they have been slowed by digitalis, stimulation of the vagus centre must also contribute. (2) Digitalis, digitalin, and digitoxin all cause a rise of blood pressure, due to constriction of the blood vessels, and a simultaneous increase in the force of the heart beats. In exceptional cases, where the strength of the cardiac beats does not increase in proportion to the peripheral constriction, the blood pressure may fall. (3) Toxic doses cause a great increase in the pulse-rate with a sudden rise in the blood pressure. This is due to paralysis of the cardio-inhibitory apparatus, since stimulation of the vagus at this period does not produce the usual slowing of the pulse-rate. (4) Very large doses of any of the

three cause the heart to stop suddenly in diastole. This is due to a direct paralysis of the cardiac muscle and not to excessive vagus stimulation; it is not prevented by previous paralysis of the inhibitory mechanism by atropine, and the vagi are always paralysed in the later stages of poisoning. The pharmacological action of both digitalin and digitoxin resembles closely, if it is not identical with, that of tincture of digitalis, and it is therefore surprising that digitalin, which is a perfectly uniform and stable body, should have the reputation of being clinically "uncertain." It is very unlikely that the substance should affect so powerfully the circulatory system of a dog and not that of man. The writers believe that the explanation of the discrepancy between the results of experiment and of clinical experience is that digitalin is given clinically in too minute doses. While comparative experiments on dogs show that gr. $\frac{1}{7}$ of digitalin corresponds to only about 16 minims of the tincture of digitalis (0.15 gram of the leaves), the dose of digitalin usually recommended is $\frac{1}{60}$ to $\frac{1}{30}$ gr. These important results require clinical confirmation. Wenzel and von Starck have reported good results with digitoxin, in doses of $\frac{1}{4}$ to $\frac{3}{4}$ mg. several times a day; but Arnold and Wood consider that it is too irritant for human medication. When given by the mouth it is liable to upset the stomach, and when injected hypodermically to cause abscesses. It is also very insoluble, and, being slowly absorbed and irregularly eliminated, has a marked tendency to cumulative action.

---

(219) Large Doses of Olive Oil in Stenosis of the Pylorus and Duodenum.

IN the Section of Surgery at the recent International Congress of Medicine, Dr. Paul Cohnheim presented a report on the therapeutic action of olive oil in cases of organic and spastic stenosis of the pylorus and duodenum, and in consequence of those conditions (gastrectasia). The paper was based on his own observations and experiments, made during the past year. He drew from them the following conclusions: (1) Cases of gastrectasia dependent not on an organic obstacle but on spasm of the pylorus, following an ulcer or fissure at the orifice of the stomach, are cured or markedly improved in a short space of time by the introduction of large doses of oil (100 to 250 grs. daily). (2) In the same way cases of pyloric or duodenal stenosis of cicatricial character accompanied by secondary gastrectasia, are cured in a relative sense by the systematic employment of large doses of oil, that is to say, the patients feel no discomfort provided they avoid all excess. In such cases the resistance caused by friction is diminished by the mechanical effect of the oil. (3) Cases of relative stenosis of the pylorus and duodenum, which are characterised by continuous secretion and pyloric spasm after the principal meals, are improved or completely cured by the oil. (4) It is well that the oil should be taken or administered through a tube during a more or less considerable period of time, thrice a day in doses of 50 c.cm. an hour before meals. If for other reasons this plan is impracticable a dose of oil (100 to 150 c.cm.) at the temperature of the body should be given once a day. The use of the oil meets three indications: It causes relaxation of the spasm, it diminishes the friction, and improves the nutrition, since the oil, even in cases of very pronounced stenosis, reaches the small intestine and is absorbed. (6) In cases of ulceration the oil acts on the spasm as a narcotic. If it be pure it has no unpleasant secondary effect; it causes neither eructations nor diarrhœa; patients take it willingly. (7) Cohnheim has hitherto not succeeded in obtaining any favourable effect from the oil in cases of cramp of the stomach of purely nervous character. This fact supplies a means of differential diagnosis between nervous and organic spasm. (8) By means of the oil cure it is possible to relieve a number of cases of pyloric stenosis with consecutive gastrectasia to such an extent that surgical intervention becomes superfluous. Cohnheim therefore thinks it is desirable to try this method of treatment in cases of stenosis of the pylorus before having recourse to operation.

PATHOLOGY.

(220) Complete Transposition of Viscera.

LENORMANT AND DURAND-VIEL (*Bull. et Mém. de la Soc. Anat. de Paris*, March, 1900) have dissected a perfect case of "situs mutatus," or complete transposition of the viscera. The patient was a woman, aged 22, who died of subacute phthisis. It is not stated that the anomaly was detected before death. There was no defect of development in any of the viscera. The right lung had three lobes, the left two, the apex of the heart pointed to the right, the arch of the aorta passed backwards from left to right, the right recurrent laryngeal passed under and turned upwards behind it, whilst the corresponding nerve on the right side turned up under the subclavian artery. The innominate artery gave off the left subclavian and common carotid, the right subclavian and common carotid each arose direct from the arch. The azygos veins were reversed in a similar manner, and it was the right vagus that ran along the front of the œsophagus. The stomach and liver were also consistently reversed, the spleen lay above the right loin, the head of the pancreas lay to the left, the tail to the right. The vena cava lay to the left of the aorta, the right ovarian vein ran into the renal vein, the left into the vena cava.

---

(221) The Detection of Typhoid Bacilli in Stools.

REMY (*Ann. de l'Inst. Pasteur*, August 25th, 1900) reviews the progress made towards the establishment of the specific *rôle* played by Eberth's bacillus in typhoid, and its distinction from the B. coli. There are still some who favour the view that the latter is not distinct from the typhoid bacillus, or that they are but varieties of one species both capable of producing the symptoms of typhoid. These opinions have been founded (1) on the alleged rarity of Eberth's bacillus in the stools; (2) on the antagonism between the two bacilli in artificial media; and (3) or the almost constant absence of the typhoid bacillus in water which has caused typhoid while the B. coli and other forms of the nature of transition types are found therein. These objections must be answered. Remy has devised a gelatine medium containing a large proportion of salts and of acid reaction, on which he was able to cultivate and separate the typhoid bacillus from the stools of 23 patients in every case successfully. He takes exception to the commonly used gelatine of Elsner on account of the inconstancy of its composition. He remarks on the importance of being able to detect with certainty the bacteria in the stools, in view of the fact that the serum reaction test cannot always be relied on. The organisms are most numerous in the second week, and gradually diminish in numbers after this; in 3 cases they were found in the stools when the clinical signs were inconclusive and the serum reaction negative, enabling the physician in charge to make a definite diagnosis, which would otherwise have been impossible.

---

(222) Etiology of Whooping-Cough.

THE pathological cause of whooping-cough is far from having been satisfactorily decided; several organisms have been described as present in the disease, but none have been shown capable of reproducing it. Luzzatto (*Centralbl. f. Bakt.*, June 30th, 1900) has studied a series of 41 cases occurring at Graz. Sputum was obtained, washed with water, and examined microscopically. Inoculations were also made on blood serum and agar plates smeared with human blood. Two different organisms were present in almost all cases, one short and thick, often in pairs, and morphologically resembling diplococcus lanceolatus and allied forms. It is probably identical with that found by Czaplewski, and shows the same bipolar staining when treated with acetic acid and weak carbol fuchsin. It was pathogenic to mice and rabbits, but intratracheal injection in a monkey produced no result. The second form commonly present was a long slender bacillus; in several cases of simple pertussis without lung signs it was present in pure culture and in great quantity. It was also found *post mortem* in the smaller bronchi in two instances. Luzzatto consists that this form is possibly specific, though he was not able to reproduce the disease by intratracheal injection in a young dog. It resembles the influenza bacillus, but is distinguished by certain characteristic appearances in cultures.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(223) Bilateral Pneumothorax.

Drasche (*Wien. med. Woch.*, June 30th, 1900) states that Skoda, in all his large experience, had never met with a single case of bilateral pneumothorax which could be diagnosed during life, and that he considered that it would be impossible to do so unless the second pneumothorax were incomplete or partial. In ten years there were 318 necropsies on cases of tuberculous pneumothorax from the Vienna General Hospital, and among these there were 11 in which the pneumothorax was bilateral. In some, perhaps the majority of cases, the second pneumothorax occurs just before death, and no diagnosis is possible. Drasche has observed 3 cases of bilateral pneumothorax 2 of which were diagnosed during life. (1) A woman, aged 22, had advanced phthisis. Pneumothorax occurred first on the right side and then, within twenty-four hours, on the left, the symptoms being on both occasions those of acute suffocation. The position of the heart was practically unaffected. The woman lived for twelve hours after the occurrence of the second pneumothorax, and a fairly thorough examination was possible. The conditions claimed by Skoda as necessary were present, though in inverted order, the second (left) pneumothorax being complete, while the first (right) pneumothorax was partial, owing to the presence of adhesions between the whole of the posterior surface of the right lung and the parietal pleura, and was limited to a portion of the anterior section of the right pleural cavity. On the left side there were three perforations of the pulmonary pleura, but so minute that the escape of air into the pleural cavity must have taken place very slowly. This doubtless contributed to the exceptional duration of life after the occurrence of the second pneumothorax. *Post mortem* the diaphragm formed a projection convex towards the peritoneal cavity, and there was no fluid in either of the pleural cavities. (2) In this case the duration of life after the establishment of bilateral pneumothorax was much shorter than in the first—namely, two hours. A phthisical man, aged 22, developed a left pneumothorax on March 15th. Under treatment he improved considerably, but on April 18th he had a sudden attack, accompanied by dyspnœa, cyanosis, and syncope. The diagnosis of an additional pneumothorax on the right side was made. The chest on the right side suddenly increased in circumference, and there was tympanitic resonance over it. *Post mortem* air escaped with a hissing sound from the pleural cavities when opened. The left lung was compressed against the vertebral column, and there was a small amount of serous fluid in the pleural cavity. In the right pleural cavity there was air only. In both lungs there were fairly large perforations of the pleura, which communicated with cavities. (3) A phthisical man, aged 26, developed left pneumothorax on June 11th. The heart was displaced considerably, showing that the air in the pleural cavity was under considerable pressure. On July 24th, while up and about, he gave a sudden cry, fell on to the bed, and died almost immediately. *Post mortem* pneumothorax, complete on both sides, was found. The perforation over the right lung was large, and so allowed the air to escape suddenly. Death was therefore instantaneous.

(224) Etiology of Chorea Minor.

T. Frolich (*Norsk. Mag. f. Laegevidensk.*, lxi, 901, September, 1900) deals with 47 cases of chorea minor treated during seven years in the hospital of the University of Christiania. The age of the patients varied from 3 to 16 years, and in 28 of them the disease had begun from seven to eleven years previously; 39 were girls and 8 boys. In 24 cases there was the family history of rheumatism or of psychical affections. Among the 47 patients there were 15 who had had rheumatic fever, either before or during the chorea, and in 16 (34 per cent.) the chorea had begun or had been accompanied by febrile phenomena with angina, articular affections, or erythema nodosum. In these 31 cases the author recognises the element of infection; in 4 others the chorea had undoubtedly followed infectious diseases, such as scarlet fever and influenza, and in the remaining 12 instances there was some slight evidence or possibility of infection. It is therefore claimed that in 80.85 per cent. of the cases the element of infection was definitely proved. Frolich specially refers to an interesting case in which the patient was first attacked with gonorrhœal vulvo-vaginitis, then with chorea, with endocarditis, and finally with monoarticular gonorrhœal rheumatism.

(225) Prognosis of Pneumonia.

Huchard, in a clinical lecture (*Journ. de Méd.*, July 10th, 1900), describes the case of a woman, aged 44, admitted under his care with pneumonia. There was a considerable degree of obesity. The disease had already lasted some days, and physical signs showed scattered patches of consolidation in the right lung. There was rusty sputum; dyspnœa was intense, but pyrexia was never a very marked symptom. Diuresis was free, but there was a considerable amount of albumen present in the urine. The patient died, and on *post-mortem* examination a right-sided pneumonia was found with some pleural effusion. The chief point shown by examination of the organs was a general fatty infiltration and degeneration. The lecturer showed that in all cases of pneumonia where adiposity is a marked feature the unhealthy condition of the organs is a very much more important factor than the actual amount of lung disease or the degree of pyrexia. It is on this account that the prognosis of pneumonia is so good early in life but so grave in later years. In cases such as this Huchard recommends bleeding to relieve the heart, and subsequently the administration of digitalis. Theobromin in small doses is also serviceable. The diet ought to be exclusively milk. Another point on which Huchard lays considerable stress is the amount of chlorides present in the urine. He states the fact that in every case of pneumonia in which the total chlorides fall below 1 gram the prognosis is very grave. Whatever be the explanation, the absence of chlorides in the organism indicates a fatal prognosis. Chlorides are absolutely necessary for gastric secretion and for the maintenance of nutrition, and accordingly Rommelaere states that those cells which chiefly require chlorides die under such conditions. The estimation of these salts, therefore, in the urine should not be neglected, as is so frequently done, as the amount of chlorides will help to indicate the prognosis. It is suggested that when chlorides are absent they should be replaced by means of salt injections, well-salted foods, etc.

(226) Tuberculous Glands in Relation to General Tuberculous Infection.

Von Noorden (*Münch. med. Woch.*, 1900, No. 4) states his opinion that now that so much attention is being paid to the subject of tuberculosis, the *rôle* of tuberculous glands as foci where the bacilli may long remain latent should be insisted on. According to different statisticians, between 70 and 90 per cent. of all children suffer at one time or another from "enlarged glands." Whether this occurs in connection with some infectious disease or with a general scrofulous habit of body, the glands usually become infected with the tubercle bacillus; they may of course be definitely tuberculous to begin with. They remain in a state of chronic inflammation, and tuberculosis of the lungs is often to be traced to the multiplication and transference of the organisms from them. Von Noorden urges the value of the tuberculin test in cases where the tuberculous nature of the swelling is not certain, and incidentally suggests its value in distinguishing such a condition from sarcoma, Hodgkin's disease, etc. He has discarded all treatment except removal by operation as early as possible, even in the first year.

SURGERY.

(227) Ligature of the Abdominal Aorta below the Diaphragm.

Keen of Philadelphia (*Amer. Journ. of the Med. Sciences*, September, 1900) records a case of ligature of the abdominal aorta just below the diaphragm, the patient surviving for forty-eight days. A man, aged 52 years, married, labourer, and with the probable history of syphilis, had suffered for two months

from severe epigastric pain radiating to the back. There was constipation and anorexia. The urine was normal. The examination of the abdomen showed a globular tumour half way between the umbilicus and the xiphoid process, and nearly 3 inches in diameter. It gave distinct expansile pulsation and a *bruit* on auscultation, and was diagnosed as an aneurysm. Operation was proposed, but the patient refused and left hospital. Five days later he was brought back in an ambulance, and examination showed in addition to the above tumour, the presence of a hæmatoma over the whole of the left side of the abdomen, and extending to 1½ inch across the linea alba. This tumour was soft, smooth, and elastic. The patient was in a condition of collapse, with very feeble pulse, but rallied under a small dose of alcohol, and an operation was at once made, as it was evident the aneurysm had ruptured and death was imminent. On opening the abdomen a large retroperitoneal hæmatoma appeared on the left side and connected with the aorta. In view of the patient's alarming condition and the certainty of fatal hæmorrhage if the clot were removed, the wound was closed. The temperature after the operation rose to 101°, and then fluctuated between 99° and 100°. The patient improved, and the effect of gelatine injections (2 per cent. in sterile normal saline solution) was tried without benefit. At the second operation (December 12th) the abdominal aorta was ligatured after exposing it above the pancreas and between it and the stomach. The working space above the aneurysm was 2 to 2½ inches. With the fingers the tissues on each side of the aorta were torn through and the vena cava was separated, four strands of disinfected floss silk were passed round, and the aorta ligatured under considerable difficulty. When this was completed pulsation ceased in the femoral artery and in the sac of the aneurysm, while the man's head, face, and neck became deeply congested and almost livid. This lividity subsided in a few hours. Ether was used in the operation, and the duration of the anæsthesia was one hour and twenty-five minutes. The abdomen was flushed out with salt solution and closed, and the legs (which were cold) were wrapped in cotton-wool and surrounded with hot-water bags. Collateral circulation was set up by the external mammary and epigastric arteries in front. On January 10th the patient sat up in bed for a while. Gelatine injections were made into the now diminished sac of the aneurysm. Eventually the patient developed chills and rigors, being a sufferer from malaria, and died 48 days after the operation. The necropsy showed that much oozing had taken place into the abdominal cavity in the neighbourhood of the ligatures which had cut through. The kidneys and liver were normal, but the bladder was the seat of myxomatous tumours, a very rare condition. A summary of cases of ligature of the aorta (13 in all) is appended to Keen's paper, the first of these being the classical one of Sir Astley Cooper.

(228) Ligature of the Aorta.

TILLAUX (*Bull. et Mém. de la Soc. de Chir. de Paris*, May 8th, 1900) reports a case of diffuse aneurysm of the left external iliac artery in a man aged 56, which was treated by median laparotomy and proximal ligature. The aneurysmal swelling which had evidently resulted from the accidental rupture of a primary aneurysm involving the distal portion of the external iliac artery and the commencement of the common femoral artery was as large as the adult head, and extended from the groin to a line a little below the level of the umbilicus. The author, finding it impossible to excise this large mass, practised ligature of a large vessel which he believed to be the common iliac artery of the left side. The patient did well for some days after this operation, but subsequently became weak and lost flesh, and presented signs of obstruction to the venous circulation in both lower extremities. The swelling increased in size and again pulsated. Before the appearance of the unfavourable symptoms neither limb presented any signs of disturbance of the circulation. Both were free from pain and swelling, and the temperature of the left was higher by half a degree than that of the right limb. The patient died on the thirty-ninth day after the date of the operation. At the necropsy it was found that the aorta just above its bifurcation had been tied, and not, as had been supposed, the common iliac artery. This case is certainly one of much interest and importance. Ligature of the aorta is a very rare operation, this being the twelfth instance on record. The death of the patient, it is pointed out, could not be attributed to the operation, as the fatal result occurred just as it would have done had such treatment not been practised.

(229) The Way to the Gasserian Ganglion.

KRAUSE (*Centralbl. f. Chir.*, No. 16, 1900) in supporting his own against rival operations for the relief of trifacial neuralgia, states that every surgeon who has attempted to extirpate the Gasserian ganglion on the living subject knows that the difficulties of the operation begin when the third branch has been exposed within the cranial cavity. At this stage it is necessary to have a clear view of the field of operation which lies between the base of the cranium and the dura mater. In order that the ganglion may be freely exposed the temporal lobe of the brain together with its covering of dura mater must to a sufficient extent, though yet with as little force as possible, be detached from the middle cranial fossa. In any other method the operator must work in the dark in a very dangerous region, and run the risk of wounding the cavernous sinus, the internal carotid, or one or more of the three motor nerves of the eye. With the object of reaching the ganglion with the least possible disturbance of the brain, the cranial cavity should be exposed at the junction of the lateral wall with the base of the skull. It is quite unnecessary, it is asserted, to remove any portion of the zygomatic arch. The author has recently modified the first stage of his operation by cutting away the base of the osseous portion of his lateral osteoplastic flap. After this flap has been formed by the use of Gigli's wire saw and division of the soft parts, it is turned down and the portion of bone forming its base is broken down. The bone between the line of fracture which usually runs across the thinnest part of the squamous portions of the temporal bone above, and the infratemporal crest below, is then cut away, and thus free access is permitted to the base of the cranium.

MIDWIFERY AND DISEASES OF WOMEN.

(230) Prolapse of Urethral Mucous Membrane.

VOILLEMIN (*Thèse de Paris*, 1900) attributes this condition to unusual laxity of the submucous connective tissue, which is normally abundant. The mucous membrane slides downwards till it appears at the meatus as a more or less circular pad. This disorder is met with in children from 2 to 12, and in women between 50 and 75; it is exceptional in adults in the prime of sexual life. The predisposing causes are said to be weakening of the tissues concerned from different reasons, frequent child-bearing, and senile involution. The most common exciting cause is straining in coughing, defæcation, and micturition. Hence prolapse occurs very rapidly in some cases. Vulvo-vaginitis, urethritis, and injuries appear to have some influence in causing this disease. The first symptom is dysuria; straining, to which the patient naturally resorts, increases the obstruction by forcing down more mucous membrane. A little red projection is then to be detected, generally on the posterior edge of the meatus; sometimes a second lies on the anterior edge; the two puzzle the observer as to their nature. More rarely at this early stage a complete circle of mucosa comes down, an appearance easier to interpret correctly. When established the prolapse causes sharp pain not only during micturition, but also in walking, and in making any effort. Coitus becomes very painful. The prolapse bleeds during micturition and at other times, but never severely. When advanced the everted mucosa becomes œdematous and very painful, small areas of slough develop, and may cause severe bleeding. Diagnosis is easy when the prolapse is complete, as a probe can be passed through the centre of the red swelling, but cannot be pushed at any point between the swelling and the urethral walls. At an early stage reduction of the prolapse is often sufficient if a compress be applied, and the patient kept at rest. Astringent lotions may prove beneficial. Cauterisation is less satisfactory, ligature not to be thought of. The thermo-cautery or galvano-cautery may be used for the removal of the mass, but excision with scissors, followed by suture of the edges of the mucous mem-

brane to the border of the meatus, is the best proceeding for the permanent cure of a large prolapse.

(231) Extraction of Living Twin 19 Minutes after Death of Mother.

Kirch (*Centralbl. f. Gynäk.*, No. 25, 1900) was called in by the friends of a shopkeeper's wife who, they said, had just died suddenly three-quarters of an hour after giving birth to a child. She was 40, and subject to mitral disease, the result of rheumatism. Very grave cardiac symptoms had developed at the end of the previous pregnancy. Kirch at once visited the patient, who lived close to his house; he found her quite dead; much sanious mucus had run out of her mouth on to the pillow. A nurse was attending the new-born child. Kirch found a fœtal leg projecting from the vulva. He at once extracted the fœtus—it was asphyxiated, but was revived; however, it died within a few hours. On the evidence of Kirch and the nurse the second twin was delivered just 19 minutes after the death of the mother. The husband stated that the patient had calculated term at three weeks later. She was working in the shop till 10 P.M.; a few minutes later pains set in, then the membranes ruptured. She was speedily put to bed and the child was at once delivered spontaneously. Dyspnœa then set in, lasting for some time, when the woman suddenly ceased to breathe, froth escaping from the mouth. Kirch arrived a little before midnight.

(232) Normal Labour after an Unnecessary Cæsarean Section.

Bissell (*Amer. Journ. of Obstet.*, April, 1900) publishes clinical details of a case very grave from an ethical aspect. A married woman, aged 19, and pregnant, was subject to prominent coccyx. Her physician did not even make an effort to deliver her with forceps; he had satisfied himself several months before term that the child could not be born through the genital canal, and openly declared that the long-looked for opportunity of his life had arrived. He performed Cæsarean section, and afterwards advised the patient to have her uterus removed, for another pregnancy, in his opinion, would kill her. She consulted Bissell about two years after the operation. The pelvic measurements were perfectly normal. The coccyx was slightly sensitive to pressure, and inclined considerably forward, but it was movable and did not diminish materially the antero-posterior diameter of the outlet. A few months later she became pregnant. Bissell attended her in labour. He found the pains strong, the head presented in the right occipito-anterior position. But a few hours later, as the head did not descend well and the pains were weak, he ruptured the membranes. This did not stimulate uterine action much, so the forceps was applied, and the child, which weighed a little under eight pounds, was delivered with comparative ease. The perineum was lacerated, but immediately repaired. Mother and child did well. Thus the previous operation, though utterly unjustifiable, did no more harm than to cause slight atony of the uterus.

(233) Cæsarean Section twice in the Same Subject.

Selhorst (*Centralbl. f. Gynäk.*, No. 27, 1900) was compelled to operate on a patient, aged 40, subject to flat, rachitic pelvis, with a conjugate of $3\frac{1}{2}$ inches. Craniotomy was practised at her first three labours. At the fourth Cæsarean section was performed, the usual vertical anterior incision being made. Nine years later Selhorst operated, as the patient was pregnant for the fifth time. He intended to do the operation before labour pains set in, but the patient came to him too late. He had great trouble in the first stage of the operation, as the uterine cicatrix adhered firmly to the abdominal wall; there were also strong adhesions to coils of small intestine, and suture-track abscess in the uterine tissue. As the serous coat of the intestines was damaged during separation of the coils, it had to be sewn over. The child was extracted alive and saved. The uterine wound, made a little to the right of the cicatrix, was closed with deep and serous sutures. The operation, on account of the difficulties in the first stage, lasted two hours. The patient did very well. Selhorst prefers the old to the fundal incision, as the subsequent contractions affect the sutures less, the hæmorrhage is not greater, and the extraction of the child quite as easy. He insists that ether is a safer anæsthetic than chloroform, especially for the child. At the first Cæsarean operation, which presumably was shorter than the second, chloroform was used, but the child was lost.

THERAPEUTICS.

(234) Glycerine as a Medium for Antiseptics.

Von Wanschheim (*Wien. klin. Woch.*, July 26th, 1900) has investigated the efficacy of various antiseptics when dissolved in glycerine. The most important results were obtained with glycerine of carbolic acid, which has been commonly substituted for carbolic oil, since Koch proved that carbolic acid lost all power as a disinfectant when mixed with oil or absolute alcohol. Glycerine itself has some power as a disinfectant both when pure and when moderately diluted with water; less than 30 per cent. glycerine has no effect on the bacterium coli or the staphylococcus aureus, and but little on the cholera vibrio; 50 to 70 per cent. glycerine kills the staphylococcus more quickly than pure glycerine, whilst pure glycerine kills the bacterium coli in a few days, but when diluted has little effect on it. Owing to this antiseptic action of glycerine it would appear theoretically to be an excellent medium for antiseptics. Practically, however, this is not the case. With three exceptions all the substances used in the writer's experiments developed a much feebler antiseptic power when diluted with glycerine than when mixed with water. This applies to solutions of sulphuric acid ($\frac{1}{2}$ per cent.), oxalic acid (1.89 per cent.), caustic potash (1.5 per cent.), carbolic acid, orthokresol, parakresol, and metakresol ($\frac{1}{2}$ per cent.), creolin (2 per cent.), lysol (2 per cent.), saprol (2 per cent.), formol (2 per cent.), tannin (10 per cent.), and thymol (1 per mille). For instance, the lysol solution with glycerine failed to kill the staphylococcus aureus after thirty minutes, while the watery solution, after the addition of an emulsion of staphylococcus, was sterile after five minutes. The three exceptions to this rule are (1) glacial acetic acid, which has the same bactericidal power with glycerine as with water, and acetone and hydrochloric acid, which are more powerful bactericides when mixed with glycerine than when diluted with water. The addition of glycerine to antiseptic soaps likewise lessens greatly their antiseptic value. Thus a 10 per cent. solution of soft soap in pure glycerine to which 5 per cent. of carbolic acid is added requires thirty minutes to destroy the staphylococcus, while a solution made with soap and water instead of water and glycerine requires only five minutes; $2\frac{1}{2}$ and 5 per cent. solutions of carbolic acid in glycerine have no antiseptic action whatever, though a 10 per cent. solution in glycerine has the same value as one of equal strength in water. It is a remarkable fact that the addition of water to solutions of carbolic acid in pure glycerine increases their antiseptic power, so that a 5 per cent. solution of carbolic acid in pure glycerine, which is useless as an antiseptic, becomes efficient when it is reduced to a $2\frac{1}{2}$ per cent. solution by the addition of an equal quantity of water. In the same way an efficient 10 per cent. solution of carbolic acid in pure glycerine becomes useless if reduced to a 5 per cent. solution by the addition of glycerine, but remains efficient if reduced to a 5 per cent. solution by the addition of water. In fact, a solution of carbolic acid in equal parts of glycerine and water is equal as a disinfectant to a solution of the same strength in water alone. Hence carbolic acid, when used as an antiseptic, should not be mixed with pure glycerine in concentrations of less than 10 per cent., or, if less concentrated solutions are required, the glycerine should be diluted with an equal quantity of water.

(235) Methylene Blue as an Analgesic.

Klemperer (quoted in *Méd. Mod.*, June 27th) has recently published his results obtained by the employment of methylene blue as an analgesic in 27 cases of sciatica. In 8 cases it failed entirely, in 6 cases the pains marvellously disappeared in five days, in the remaining 13 the sciatica resisted the treatment for several weeks, but the pains were less frequent and the patients were enabled to sleep at night. Three to six capsules containing 0.45 gram (about 7 grs.) were given daily. Slight gastric disturbances occurred, but they

involved no serious inconvenience, and any pain during micturition was easily annulled by adding a little nutmeg to each dose. The writer has found the medicament very useful in tabes, neuralgia, and myalgia in diminishing the intensity of the pains. In these conditions it is best to commence with 0.25 gram (4 grs.) twice a day, and very gradually increase the dose up to 1 gram (15½ grs.) or more. The substance must be absolutely pure, otherwise gastric, toxic, and diarrhœic troubles will follow. It should be administered in well-made cachets, so as to avoid any coloration of the oral cavity. The patient should be warned of the urinary change of colour, and that some slight vesical spasm and dysuria may occur. The action of the blue causes at first a numbness, passing gradually into analgesia; its action is rapid, but of not long duration. Hence it is necessary to continue the medication whilst any pain is felt. Local effects can also be obtained, but the disadvantage of its colouring power has not yet been overcome. It has been proposed also to use the blue in subcutaneous injections, but at present there have been no experiences published. It is claimed that methylene blue in excessive doses does not cause the depression, etc., of increased amounts of the ordinary analgesics, and is worthy of extended use.

(236) Arsenic in Infantile Eczema.

Neuberger (*Archiv f. Derm. und Syphilis*, vol. xlvii, 1899) has had good results from the treatment of chronic eczema in infants by the internal administration of arsenic. To infants of 2 years and upwards he gives one drop of a mixture of equal parts of Fowler's solution and distilled water. This is given in milk after the midday meal, and gradually increased to six or seven drops. In sucklings and infants under 2 years of age he gives one drop of Fowler's solution of the strength of 1 in 3, and this is gradually increased to five drops. The infants are said to take the drug well, and no bad symptoms were observed. The treatment usually lasts sixteen or eighteen weeks, and relapses sometimes occur.

(237) Treatment of Gonorrhœal Arthritis.

Mackenzie Forbes (*Amer. Journ. of Cut. and Gen. Urinary Diseases*, January, 1900) considers that the rational treatment of urethral rheumatism consists in local treatment of the urethra combined with general treatment of the arthritis. He points out that urethral arthritis is either due to the migration of the gonococcus or some other microbe from the urethra to the joints, or to the absorption of their toxins. Hence (1) if it is due to the migration of gonococci to the joint, as we know from experimental evidence and from the fact that they have been rarely found except in acute cases, gonococci do not flourish in the joint, and therefore the rational treatment is to cut off the source of supply in the urethra. (2) If it is due to the migration of other microbes or to the absorption of toxins, we may assume that all exacerbations are due to reinfection of the joint from the urethra. Here the same treatment applies. In order to cure a urethral arthritis the urethra must be kept as sterile as possible, and its mucous membrane must be without abrasion. The urethral tract must be carefully examined and the lesions found treated till the canal is in a healthy condition. This treatment may have to be continued after the joints are well. The local treatment carried out by the author in ordinary cases of anterior and posterior urethritis consists in the internal administration of a pill containing methyl blue and boric acid, or urotropin combined with lavage with permanganate of potash and injections and instillations of protargol.

(238) Venesection in Heat-stroke.

C. Klein (*Münch. med. Woch.*, July 3rd, 1900) observed a case of heat-stroke where venesection gave prompt relief. A powerful, temperate, and healthy coal-heaver, aged 28, acted temporarily as stoker on board ship. After a few hours' work he suddenly became unconscious and was seized with violent general convulsions. He was brought on deck, ice was applied, and artificial respiration was carried out as far as the convulsions permitted. Chloroform inhalation was tried, but abandoned as it had a bad effect on the respiration. The convulsions increased in violence, and four sailors could hold the man with difficulty. The pulse, at first hard and full, became thready and intermittent; the respiration became more and more laboured, and there was great cyanosis. The man was evidently dying of œdema of the lungs; Klein therefore abstracted about 8 ounces of blood. The effect was immediate; the pulse and respiration improved, the convulsions gradually ceased, and the cyanosis was replaced by pallor. After a ten-hours' peaceful sleep the patient awoke weak, but hungry, and in a few days had recovered completely.

PATHOLOGY.

(239) The Action of Diphtheria Toxin on the Nervous System.

Bielschowsky and Nartowski (*Neurol. Centralbl.*, July 1st, 1900) describe experiments which they have recently carried out in Mendel's laboratory. The pathological changes have been located in three situations—the peripheral nerves, the spinal cord (parenchymatous and interstitial myelitis, with secondary changes in the nerves and muscles), and the muscles. The authors injected sterile diphtheria toxin into white mice, rabbits, and guinea-pigs. Large doses produced rapid death, with anatomical evidence both of general intoxication and of a special action on the vascular system. The animals which survived this stage developed, eight or ten days after the injection, more or less typical post-diphtherial palsy. The vessels were found quite full and with pathological changes in their walls leading to scattered foci of hæmorrhage. There was no sign of meningitis or encephalitis, nor were the nerve cells of the brain or cord with a few isolated exceptions affected. Preparations by Marchi's method showed nothing noteworthy in the brain or cord, but extensive degeneration of the myelin sheaths of the peripheral nerves; this was confirmed by Weigert's procedure. The muscle fibres were the seat of fatty change. The conclusion is drawn that the essential lesion is parenchymatous degeneration of the peripheral nerves; the slight changes in the anterior horn cells are held to be secondary or of cachetic origin; while the vascular alterations play but a subordinate *rôle* in the pathogeny of post-diphtherial palsy.

(240) Toxic Nephritis and Uræmia.

Lindemann (*Centralbl. f. allgem. Path.*, No. 9, 1900) has conducted an interesting series of experiments on this subject. A serum is prepared by injecting into an animal of one species (A) the finely pounded kidney substance of another series (B); the serum taken from B is found to act directly as a renal poison when injected into animals of species A. This "nepholytic" action is, however, much more powerful when the kidney substance injected into B is diseased, as, for instance, by acute nephritis. Lindemann produced acute nephritis in dogs by administering potassium chromate, and in experiments in part complementary to the above he found that the serum of these dogs acted as a strong kidney toxin, in others, producing albuminuria, suppression of urine and uræmia, in lethal doses. He proposes further investigation to discover what element of the serum is the active agent in producing these symptoms. No potassium chromate is present, and normal blood serum has no such effect.

(241) Minute Changes in Varicose Veins.

Janni (*Langenbeck's Archiv*, Bd. lxi, Part 1) observes that there is a considerable difference between the accounts of these changes hitherto published. He has taken the enlarged veins of the spermatic cord as the material for his investigation. In these are to be observed not only degenerative and regressive changes brought about by passive distension, but also, especially in the early stages of the enlargement, considerable connective tissue proliferation, which chiefly has its site in the tunica intima. It shows itself in the form of a nodular or flaky endophlebitis. At the larger nodes there is also an increase in the fibres of the inner elastic layers. Where the connective tissue nodes and plates are well marked the process may extend to the middle coat. Janni does not agree with Epstein that these changes are compensatory, but considers them of the essence of the disease, a true hyperplasia.

AN EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

(242) Kernig's Sign.

Roglet (*Journ. de Méd.*, October 10th, 1900) has made an extensive series of observations on the subject of Kernig's sign. As is now generally known, this sign consists in the impossibility of completely extending the leg on the thigh when in the sitting posture, in a patient suffering from certain meningeal diseases. There is a certain amount of contracture of the flexors of the leg. This contracture, on the other hand, disappears, and complete extension can be obtained when the patient is lying on the back. It is therefore easy to elicit this phenomenon if, after having ascertained the absence of all contracture in the supine position, the patient is made to sit up with his legs hanging free, or even sitting up in bed. Certain precautions are therefore necessary. The observer must see that the patient sits straight upright, and does not lean to one side or the other, and that the thighs form a right angle with the trunk, certainly not less. Disregard of this point may lead to considerable error. The attempt to obtain Kernig's sign is sometimes attended with considerable pain. The amount of extension obtained at the knee varies considerably. When Kernig's sign is well marked it is impossible to exceed a right angle; when slight an obtuse angle equal to 135 degrees; but intermediate degrees may be obtained. Nor is the sign always bilateral; occasionally it has been observed on one side only, or to an unequal extent in both limbs. The intensity of the phenomenon may vary from day to day, or may even disappear completely. To be therefore sure of its non-existence several observations are necessary. Kernig's sign may appear at the same time as the other symptoms, rigidity of the neck, ocular symptoms, contracture, etc., but most usually it appears about the third or fourth day of the disease. In tuberculous meningitis its appearance is most delayed. It is very rare for it to be the only symptom present. Kernig's sign may disappear at variable periods. In meningitis ending fatally, it may persist up to the end, but in other cases it may disappear shortly before death, especially in cases where, owing to coma, there is general flaccidity, and all contractures give place to paralysis. It is under such circumstances that Kernig's sign has been missed in several cases of meningitis. The diagnostic value of this sign is considerable, as it has been met with in 85 to 90 per cent. in cases of meningitis. It is, however, present in other conditions with meningeal inflammation for example, meningeal hæmorrhage and cerebral abscess—but this seems to be exceptional. Its value is reduced, therefore, by the fact that it rarely appears at the beginning of the case or occurs alone. The diagnosis is consequently in many cases apparent independent of this sign. Roglet explains the phenomenon as follows: In a person in a sitting posture with the thighs flexed to some degree, and the trunk of the legs extended, the flexor muscles are on stretch, and their elasticity is soon exhausted. If under the influence of spinal irritation and irritation of the spinal roots, where this may be due to increase of intraspinal pressure or to the presence of purulent exudation, there is naturally produced some increase of muscular tonicity. This diminishes the elasticity and length of the flexor fibres, which then become too short to allow of extension of the leg on the thigh, and thus the sign is produced.

(243) Polymyositis.

Th. Struppler (*Deut. Arch. f. klin. Med.*, 1900, vol. lxviii, p. 407) records a case of acute hæmorrhagic polymyositis in a man aged 33. The commencement was sudden, shortly before admission to the hospital. On admission the swelling had already somewhat subsided in the lower extremities, but the supinator and extensor muscles of the left upper extremity were much involved, and the symptoms in the right arm were beginning. The tongue, throat, trachea, bronchi, and lungs were also affected, and the man died within six days from the commencement of the illness from acute œdema of the larynx. The fever, swelling of the spleen, pleurisy, and multiple hæmorrhages in this case confirm the opinion, suggested by previous cases, that the disease is of an acute infectious nature. No cause for the infection could be discovered. The heart was unaffected, but later on in the disease, had the patient lived longer, it might have shown the pathological changes described by Bauer. The present case, therefore, furnishes no evidence against the view that the heart is generally involved in acute hæmorrhagic polymyositis. Struppler also describes a case of "relapsing acute rheumatic polymyositis," recalling the features of "dermatomyositis." The patient, a young man aged 24, had erythema multiforme and myositis of both gastrocnemii, the peroneus brevis, and (an undescribed feature) of the left temporal and both frontal muscles (chiefly right). He also suffered from acute articular rheumatism, with old cardiac valvular disease, chronic parenchymatous nephritis, and chronic pulmonary tuberculosis. The patient left the hospital, and the termination of the muscular affection is unfortunately not given.

(244) An Unusual Symptom in Helminthiasis.

Papi (*Gazz. degli Osped.*, June 10th, 1900) records the case of a child, aged 18 months, suffering from gastro-enteritis and cough, who developed Cheyne-Stokes respiration. No cause could be detected for this in the thorax, the heart was normal, and the lungs only contained a few *râles* of bronchitic character. The child vomited ascarides, after which the respiration became rather better, but still had a Cheyne-Stokes character, until free purging and vermifuge treatment was adopted. As soon as the worms were expelled the respiration became normal. The author believes the Cheyne-Stokes phenomenon was due to some poison secreted by the ascarides.

(245) Retrobulbar Hydatid.

Lavagna (*Giorn. dell. R. Accad. di Med. Torin.*, July, 1900) records the case of a child, aged 2½, from whom a hydatid cyst situated behind the left eye was successfully removed. The child was first seen December 16th, 1898, with a history of left ptosis and exophthalmos of three months' duration. On examination a tumour was felt behind the eye; no distinct fluctuation could be detected, no pulsation, nor any inflammatory symptoms. When the right eye was bandaged the child was able to play as if it saw with both eyes. There was a slight degree of optic neuritis in the left eye. The child had been particularly fond of dogs. On December 22nd, 1898, the cyst, which proved to be a double hydatid, was successfully removed. A small rubber drainage tube was left in for twenty days. When last seen (July, 1900) the child could see quite well with the left eye, shows no trace of the operation, and no symptoms of return.

SURGERY.

(246) The Treatment of Inoperable Cancers.

Czerny (*Centralbl. f. Chir.*, No. 28, 1900) insists on the importance of careful and methodical treatment in cases of recurrent and inoperable forms of malignant growth. The large proportion of cases of carcinoma and sarcoma unamenable *ab initio* to operative treatment, and the very frequent instances of recurrence of malignant disease after operation, are undoubted facts that render it necessary for medical men to direct attention to the most suitable means of alleviating the sad condition of patients in such unfortunate circumstances. Unfortunately, it is stated, in too many instances the medical man, when he finds that there is no prospect of cure by operation, ceases to take a deep interest in the case, and many, particularly the younger members of the profession, are wanting in a knowledge of simple methods of palliative therapeutics, and also of that professional diplomacy which is capable of doing so much to relieve their wretched lot, and to secure their confidence. Czerny, using the term "inoperable" in reference to the inadequacy of surgical treatment for radical cure, points out that much good may be done in cases of incurable cancer by palliative operations such as gastro-enterostomy, intestinal anastomosis, gastrostomy, and colotomy. In cases of ulcerating malignant growth the profuse discharge and occasional bleeding may be arrested

and the severe pain relieved by the application of the actual cautery and caustics and the free use of the sharp spoon. Formalin in solutions from 10 to 40 per cent. is recommended as a good local application to an ichorous and hæmorrhagic ulcer. In the local treatment of inflamed and very painful open cancers, aseptic powders, such as boric acid, salicylate of soda, orthoform, and iodoform, are regarded as indispensable. In concluding his paper, Czerny states his belief that the effectual cure of cancer by a general and medicinal method of treatment, prospects of which are afforded by the occasional good results of artificially-produced erysipelas in cases of sarcoma, cannot be brought about by any means short of systematic and centralised research and by the more general establishing of special hospitals for cancer like those that are at present to be found only in London and New York.

(247) Complete Prolapse of the Rectum.

Gérard Marchant (*Bull. et Mém. de la Soc. de Chir. de Paris*, April 17th, 1900) supports the view recently expressed by Ludlow, that prolapse of the rectum is due to yielding of the wall of the intestine at the level of the vesico-rectal *cul-de-sac*, this yielding being caused by pressure of the small intestines contained within the pouch of Douglas; by constipation, giving rise to weakness of the coats of the rectum, and probably by some congenital malformation of the *cul-de-sac*. The anterior wall of the rectum is first protruded into the intestinal lumen, and in course of time, as it descends, carries with it the lateral and posterior walls, so as to form a complete prolapse. Marchant points out that the reflection of the peritoneum over the anterior wall of the rectum at the *cul-de-sac*, corresponds to the valvular fold of this portion of the intestine known as the third sphincter, or the sphincter of Nélaton. This sphincter, it is stated, always forms the lower extremity of the protrusion in fully-developed forms of rectal prolapse. If this view of the pathogeny of prolapse be correct, it would be necessary to modify the present method of dealing with this condition, as it must be evident that resection of the protruded portion of intestine is a futile as well as a dangerous operation. The surgical treatment, it is held, should be directed with the objects of diminishing the length and width of the protruded portion of rectum, and of suspending this to some unyielding structure. Reference is made to a case successfully treated by Pauchet, in which this surgeon performed an operation devised by Marchant, and described under the title of "recto-coccypexy." This operation consists in (1) in contracting the anus by excising a part of its circumference; (2) in diminishing the capacity of the prolapsed portion of intestine by folding its walls by sutures passed both vertically and from side to side; and (3) by fixing the contracted intestine to the posterior wall of the pelvic skeleton.

(248) Surgical Treatment of Rectal Prolapse.

W. Krajewski (*Przeglad Chirurgiczny*, iv, 539, 1900) discusses in detail the various operative procedures for rectal prolapse. With regard to the different measures for narrowing the anus and rectum, such as the excision of radiating folds of the anus and posterior rectorraphy, with or without torsion of the lower end of the intestine, he comes to the conclusion that they only remove one morbid condition, the anal relaxation, leaving untouched the weakened suspensory apparatus and the dilatation of the rectal ampulla. He gives details of 5 cases in which he operated by another method, that, namely, of amputation of the prolapsed portion of Mikulicz's operation, but sums up on the whole against it, as after it the prolapse may be reproduced, and the cicatrices may cause rectal rupture or stenosis. This operation is to be restricted to the cases in which the prolapse is irreducible or complicated by ulceration or necrosis. For all other cases he is inclined to recommend fixation of the prolapsed intestine either below (rectococcypexis) or above (colopexis) in such a position as will prevent its descent; but the operations of Gérard-Marchand and Jannel, which aim at the accomplishment of these manœuvres, have yet to be tested and probably modified.

(249) Cæcum Adherent to Vas Deferens.

Célos (*Bull. et Mém. de la Soc. Anat. de Paris*, March, 1900) detected this condition in the body of a man, aged 75, who had died of interstitial nephritis without any signs or clinical history of appendicitis. On lifting up the cæcum at the necropsy the vas deferens was stretched till the testis was pulled upon. On further dissection the vas appeared closely united to the fundus of the cæcum by numerous adhesions, which also bound down a little white cord, the vermiform appendix greatly contracted. Its orifice was obliterated. The extremity of the appendix reached to within a third of an inch of the vas. It is not rare to find the appendix adherent to the vas; in this case the cæcum itself adhered to the seminal duct. The vas, strictly speaking, ran high in this case, so that it was not a case of the cæcum being drawn down to the vas, but just the reverse. Old perityphlitis had involved the vas, which was abnormally near the seat of disease. Dieulafoy published a case of adhesion of the appendix to the cord, manifested by fits of testicular pain, as in renal colic.

MIDWIFERY AND DISEASES OF WOMEN.

(250) Ovariotomy Statistics.

Bürger (*Festschrift für Prof. Schauta: Monats. f. Geburtsh. u. Gynäk*) publishes statistics of 394 ovariotomies performed in fifteen years in Schauta's wards. Every case was performed as early as possible with aseptic precautions. Schauta seemed to make a point of removing the tumour undiminished in size whenever it could be managed. Silk was usually employed for suture and ligature, and the abdominal wound was closed in three layers. In 78 per cent. of the cases only one ovary was affected. The right and the left ovary were the seat of tumour with about equal frequency. The mortality came to 9.5 per cent.; of the recoveries, 97 per cent. were permanently cured, and 76 per cent. had sound abdominal cicatrices. Good as these results proved, Schauta always endeavours to remove ovarian tumours through the vagina whenever practicable, but of the last 60 vaginal ovariotomies the tumour was totally extirpated in 19; in 10 this method had to be given up and the abdominal operation performed. The mortality of the purely vaginal operations that were completed was 1.94 per cent.

(251) Gonorrhœa in the Genital Tract of a Newborn Child.

Aichel (*Hegar's Beiträge*, vol. ii, Part 2, 1900) observed this case. The mother had gonorrhœal discharge from the urethra, verified by microscopic examination. Four days after birth the infant had swelling with redness about the vagina; from that date to the tenth day there was purulent discharge which for the three succeeding days was sanious. The infant's general condition remained good, no inflammation of the surrounding connective tissue followed. Plenty of gonococci were detected in the pus, which when cultured yielded diplococci and bacillus coli communis. Aichel suspects that gonorrhœa of the vulva may be frequent in the infant, and that it ascends quickly, the vulva healing. It may explain the bleeding and erosions not rare in infants; also it may cause the so-called "congenital" atresia vaginæ.

(252) Extrauterine Fœtal Bones Retained Seventeen Years.

Klingensmith (*Amer. Journ. Obstet.*, September, 1900) reports the case of a patient, aged 53, who suffered from profuse diarrhœa and pricking pains during the latter half of 1896. The fæces seemed rough and sandy. In January, 1897, one cranial and one long bone were removed from the rectum; in March and August of that year more bones were extracted through the rectnm. Altogether twenty-four bones came away. The patient had borne four children, one labour was a twin birth. After the third labour she became pregnant again and miscarried in 1879. A few months later she seemed to become pregnant, colicky pains set in at the tenth week, severe enough to be remembered. Fœtal movements were never strong. In August, 1880, the membranes ruptured, the amniotic fluid gradually escaping. There were no labour pains. The abdomen diminished in size and a fœtid discharge set in and continued for one year, after which time menstruation became regular again. From 1882 to 1896, when the diarrhœa set in, the patient experienced no particular inconvenience.

(253) The Danger of a Pyosalpinx.

Toth (*Centralbl. f. Gynäk.*, No. 38, 1900) operated on a woman, aged 43, amputating the vaginal portion of the cervix for a fibroid as big as an apple in the anterior lip. The wound was sutured. On the sixth day the temperature rose to 101°; the wound was examined; then the temperature increased to 105°, with a rigor. Next morning it fell to 99°; the sutures were removed; the wound was sloughy at several points. Peritonitis set in, and death occurred on the eleventh day. At the necropsy purulent peritonitis was discovered, and buried in old adhesions a pyosalpinx lay on each side of the uterus; there was a circumscribed cavity full of pus outside the right pyosalpinx, in the adhesions, and this was undoubtedly the starting point of the diffused suppurative peritonitis. But there was no communication between the field of operation and the pyosalpinx; the wound and the parametrium were alike free from necrotic processes. Toth suspects that during the operation or the examination when fever set in the tubes may have been stretched and detached from their adhesions, so that the suppurative process was set up again. Tunkai related a similar case. Tauffer, in the discussion at Buda Pesth on these two cases, remarked that absolute asepsis is impossible in a vaginal operation, whilst in Toth's cases there were two suppurating foci. He had seen sloughing of vaginal wounds in a clinic where soap and soft brushes were applied to the parts for several days before operation, then sublimate solutions thrown up, and lastly iodoform packed into the vagina. Doktor remarked that we lay too great stress on killing bacteria before the operation and too little on careful attention to the wound afterwards.

(254) Pregnancy and Alexander's Operation.

Stratz (*Centralbl. f. Gynäk.*, No. 28, 1900) read at the April meeting of the Netherlands Obstetrical Society a case where a patient under his care had undergone Alexander's operation four years previously. She was 36 and had been seven times pregnant. For a few years she suffered from gall-stone colic. Recently she had been at sea for a month and owing to uncontrollable vomiting had to be fed with nutrient enemata. Gall-stone colic further troubled her during the voyage. The period had last been seen on July 4th, 1899. On March 6th, 1900, she was admitted into hospital at the end of the eighth month of pregnancy. There was icterus, pulse 72, temperature subnormal. The right round ligament was very tense, thickened, and painful. The vertex presented in the first position. Morphine was given, then the violent colic which distressed her ceased, and a large gall stone was detected in a motion. But the vomiting which accompanied the colic continued unabated, and, as the patient was much reduced, labour was induced on March 14th. The os was easily dilated with the finger and a bullet forceps. Braxton Hicks's version was then practised, and one foot brought down with the bullet forceps. Directly the waters broke the tendency to vomit ceased but solid food was rejected. The child, a female, was very sickly and asphyxiated at birth. It bled from a wound made by the forceps. Two hours later manual extraction of the placenta was effected; it set up nausea. Next day the patient could keep down fluid nourishment and oysters. Thenceforth she did well and never vomited. The child died on the second day. Stratz feels sure that the trouble was due to Alexander's operation, though performed in this case by a great authority. On the fourteenth day of the puerperium a hæmatoma could still be detected in the right round ligament. Stratz attended at the labour of another case where the same operation had been done, and detected a bilateral inguinal hernia.

(255) Pregnancy with Gangrenous Fibroid of Uterus.

Münchmeyer (*Centralbl. f. Gynäk.*, No. 27, 1900) recently exhibited at a Society in Dresden a myomatous uterus of the size of a man's head. In its cavity was found a normal well-developed ovum of the second month, with a healthy fœtus, yet a gangrenous interstitial myoma projected into the cavity. As the catamenia were irregular before the operation pregnancy was suspected.

THERAPEUTICS.

(256) Diphtherial Paralysis and Antitoxin.

Ransom (*Journ. Pathol.*, vol. vi., No. iv.) gives the results of experiments on this subject. The investigation was suggested by statements which have been made to the effect that cases of post-diphtherial paralysis are more frequent now than they were before antitoxin was introduced. The experiments showed that: (1) Paralysis is to be expected after injection of about one-fourth of the minimum lethal dose; after one-half it always occurs; doses below one-fourth may cause paralysis but not constantly, and below one-eighth it was not produced. (2) Neutralised mixtures of toxin and antitoxin do not cause paralysis, but when the mixture contains a deficiency of antitoxin, paralysis occurs and the greater the discrepancy the severer is the paralysis. (3) When the antitoxin is administered fifteen to twenty-two hours after intoxication, even the largest doses do not with certainty prevent paralysis where the dose of toxin approaches the minimum lethal dose. With increased doses of antitoxin, however, the paralyses decrease in severity. Small doses of antitoxin have no evident effect in diminishing the paralysis. The bearing of these results on the administration of antitoxin to human beings is pointed out by the author. Large doses given early should influence favourably or prevent paralysis, especially such general symptoms as heart failure. If paralysis is more frequently noted in these days it must be due to the fact that many of the severer cases are rescued by the antitoxin and develop these symptoms, whereas without the antitoxin they would not have survived. Severe cases are likely to be followed by some paralysis in spite of large doses of antitoxin. Guinea-pigs were used for the experiments, as they are liable to characteristic ost-diphtherial paralysis.

(257) Treatment of Sciatica.

Ghietti (*Gazz. degli Osped.*, September 23rd, 1900) in two obstinate cases of sciatica, of many years' duration, has tried with complete success injection of salophen. An aqueous alkaline solution was made, of which each 10 c.cm. contained 1 gram of salophen. This was injected into the gluteal muscles every other day. After the sixth injection the pain was materially lessened, and had practically gone after the eleventh. The patients were kept in bed until the fifteenth injection. Thirty injections were given in all, after which the patients, feeling quite well, wished to leave the hospital. They were seen fourteen months later, and had remained quite free from pain for the whole of the time. Salophen is supposed to split up into salicylic acid (of which it contains 51 per cent.) and acetylparamidophenol, when taken into the body.

(258) Ichthalbin in Intestinal Disorders.

Rolly, of the Heidelberg Polyclinic (*Merck's Archives*, August, 1900), in order to obtain definite knowledge of the action of ichthalbin, made observations on 28 cases of intestinal diseases, with the following results: (*a*) Simple chronic enteritis (8 cases). The following case is typical: F. D., aged 5½ years; chronic enteritis, anæmia, and pseudo-ascites; constant diarrhœa for last three and a-half years; oat gruel, acorn cacao, tannin preparations, etc., were only of transient value; bodily emaciation with abnormal increase in size of abdomen; the bowels were distended and the stools loose, frequent, and fœtid. Was treated with 8 grs. of ichthalbin three times a day, the diet remaining the same as before treatment. The diarrhœa disappeared and the motions were more natural. On suspending the ichthalbin, diarrhœa ensued on the four days following, but disappeared on administering doses of 23 grs. ichthalbin daily for three days. From this time onward an increase of 26 ozs. in body weight took place in two weeks. Treatment was continued, and nine months after the patient presented a very good appearance, having gained weight and health. Small doses of the medicine were still taken from time to time. In the other 7 cases there was also improvement of the catarrh. (*b*) Chronic enteritis with peritonitis (3 cases). The following case is typical: H. H., aged 4 years; chronic enteritis, with severe catarrh of the colon and peritoneal exudation and tuberculous peritonitis. (A sister of the patient had died of tuberculosis, and so had the grandparents.) Patient suffered from a year and a-half with alternate diarrhœa and constipation. Of late there was great increase in size of abdomen, with

emaciation of the entire body; complete anorexia; much mucus in the stools. Only a transitory slight improvement with resorcin, diet, and inunctions of green soap. Forty-five grains of icthalbin were prescribed three times a day, the diet being as before. In a week the stools were regular, two or three times daily, and of semi-solid consistence. The appetite was remarkably increased, and patient constantly desired food. The peritoneal exudation—which before reached to a finger's breadth above the navel in the recumbent position—had decreased. Improvement continued, action of bowels once or twice daily; the body weight increased 3 lbs. in five weeks. The patient still takes a little of the medicine daily. Estimates of the ethylsulphates in urine showed that shortly after the taking of icthalbin there was a decided decrease in intestinal fermentation. (*c*) Chronic enteritis with tuberculosis (5 cases). Satisfactory results had already been obtained in Neumann's clinic in this class of cases, and Kilburn Jones had also recorded good results in chronic intestinal catarrh with tuberculosis. In Rolly's 5 cases, all improved and gained weight, but 3 of them died subsequently of miliary tuberculosis at the ages of $2\frac{1}{3}$, 3, and $2\frac{1}{2}$ years. (*d*) Subacute gastric and intestinal catarrh (12 cases). The medicine exerted a beneficial effect on the catarrh; appetites and general conditions improved, the stools became natural, and, after treatment—8 to 15 grs. thrice daily—for three to eight days, were discharged cured.

(259) Iodipin in Syphilis.

RADESTOCK (*Therap. Monats.*, 1899, page 551) draws attention to a new preparation of iodine—iodipin—which is a combination of iodine with oil of sesamum (10 per cent. of iodine). The compound is said to be stable, and is recommended for tertiary syphilis in place of potassium iodide. It is said to cause no marked iodism or gastric troubles, and to have a more lasting effect than the iodides. It is administered internally in doses of 40 to 50 grams, or by inunction. The author quotes two severe cases, one of acquired and one of hereditary syphilis, which cleared up under this treatment after resisting the usual methods. Klingmüller (*Berl. klin. Woch.*, 1899, p. 540) also reports favourably on the drug, and recommends its use by subcutaneous injections of a 10 per cent. solution in doses of 20 c.cm. every other day.

(260) Anæsthesia by Means of Intramedullary Injections of Cocaine.

MANEGA (*Rif. Med.*, October 11th-12th, 1900) has practised the above method of inducing anæsthesia in 30 cases. He uses a strong needle about 8 cm. long to pierce the medullary canal, and before injecting the cocaine (a 2 per cent. solution containing about 19 to 20 milligrammes) he makes sure of the entrance of the needle into the canal by waiting for the exit of a few drops of cerebro-spinal fluid. The patient being seated, a transverse line is drawn between the posterior superior iliac spines, and the spinal canal pierced just below this. Complete anæsthesia of the parts supplied by the nerves coming from the spinal cord in the lower two-thirds of the body follows in about ten minutes. No serious symptoms have been observed; merely a certain amount of nausea, vomiting, and headache. The author's operations lasted from half an hour to an hour and a-half, and the anæsthesia was well maintained the whole time. Of the more serious operations were 4 laparotomies (ovariotomy, excision of the head of the pancreas, hysteropexy, and purulent peritonitis), 2 were severe operations on the kidney, and 10 were for hernia. The patients ranged from 5 to 75 years in age.

PATHOLOGY.

(261) Gastro-intestinal Disinfection.

NICATI and others have shown that to produce general infection by injection of cholera cultures into the duodenum some injury to the intestine is necessary, and that otherwise the bacteria die in the intestine. Schutz (*Berl. klin. Woch.*, June 18th, 1900) has investigated this intestinal disinfectant action on the cholera vibrio. In the stools of dogs fed with cultures of the bacillus none of the organisms were to be found; the gastric juice was then excluded by a cannula placed in the duodenum, and the culture was introduced directly into the latter; in this case, also, the stools were free, the rectal contents were also free, the colon gave only one colony, and in the small intestine cultures were only obtained with difficulty. Exactly similar results were obtained by investigating the intestinal contents of animals to whose food the cultures were added, showing that the hydrochloric acid of the gastric juice does not take the active part in disinfection that has been assigned to it. An interesting discovery was that after castor-oil and calomel (especially the latter) the bacilli are found even in the stools, and the ordinary bacteria were also more numerous. It is to be deduced from the experiments that, apart from disinfection by the gastric juice, which is very transient in its action, there is some natural antiseptic excreted by, or in some other way connected with, the small intestine, which is active in the absence of both hydrochloric acid and bile, and probably of the nature of a ferment, as suggested by Buchner. With this antiseptic action calomel interferes; and though Schutz does not argue that artificial disinfection should be given up, yet he maintains that it rests on a very uncertain basis.

(262) Lead Poisoning in Childhood.

HAHN (*Arch. f. Kinderheilk.*, Bd. xxviii, Ht. 3) points out that the pathology of lead poisoning in children is very different from the course in adults. It is very infrequent and possibly often overlooked. The effect is almost confined to the nervous system, and in no case have the well-known symptoms of colic, anæmia, and the blue line on the gums been recorded. He relates the case of a child treated for a month with Hebra's ointment for eczema of the head, who developed symptoms of cerebral compression, became comatose, and died. A considerable quantity of lead was found in the brain by chemical examination. The author has collected all the recorded cases in children, and draws attention to the fact that the intoxication is becoming more generally recognised. Most cases have been due to the application of plasters containing lead. Many of the ordinary sticking plasters contain a small quantity. He remarks that it is strange that no case arising from the sucking of lead soldiers has yet been recorded.

(263) Infection.

RADZIEVSKY (*Centralbl. f. Bakt.*, August 22nd, 1900) includes under the term "infection" all the effects which follow the entrance of micro-organisms into the animal body. All authors ascribe the most important changes to the action of specific poisons produced during the development of the infecting organism. Some, however, consider these poisons decomposition products of the action of the organism on the tissues, while others have brought evidence to show that there is active poisonous matter in the living structure of the organisms themselves. This active poison is, according to some, secreted as a normal vital act of the organisms, while others believe that the appearance of the poison follows their decay and dissolution. Cantani and Pfeiffer believe that the organisms are killed by contact with living cells, and that the dead specimens are taken up and dissolved, the contained poison being thus carried into the circulation. Radzievsky has observed the course of events in fatal infection with bacillus coli. In the first stage the multiplication of organisms is in the ascendant, in the second stage their destruction is remarkable, and involves a steadily increasing number of examples. When a culture not specially virulent is injected the number of living specimens is notably decreased before death. Bactericidal substances are formed which kill the microbes, and, the dead bodies being dissolved, the bacterial poison gains access to the general circulation, and produces the clinical signs of infection. The destruction of the microbes is extra-cellular in the fluid elements of the tissue. The microscopical changes found after infection with a dead culture are the same as those to be observed in infection with living organisms. The author's observations point to there being important toxic substances in the structure of bacteria which are largely responsible, when the latter are killed and dissolved, for the clinical signs of infection.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(264) Disturbances of Respiration in Hemiplegics.

Boeri and Simonelli (*Gazz. degli Osped.*, October 7th, 1900) have studied the respiratory movements in 61 cases of hemiplegia. In almost every case respiration was both absolutely and relatively diminished; in 49 of the cases there was a distinct difference in movement between the two sides; in 39 the movement was less on the paralysed side, and in 10 it was more marked and full when compared with the sound side. These differences applied not only to exaggerated voluntary efforts, but to quiet automatic respiratory movements. The nature of the cerebral lesion made no difference. The difference was as a rule more marked in proportion to the degree of paralysis, especially when the greatest stress was seen in the upper limbs. In some cases a unilateral arrhythmia was observed. The authors believe there is a superior cortical centre for respiration, probably situated somewhere near the motor centre for the upper limb, to which the medulla centre is subservient. The greater frequency of respiration on the paralysed side is explained by supposing that this centre is excited by irritation rather than depressed. Automatic respiration could be carried on by the medulla centre, but when voluntary the cortical centre would be called into play.

(265) Brown-Sequard's Paralysis.

Woods of Philadelphia (*Amer. Journ. the Med. Sci*, August, 1900) records a case with the clinical symptoms exactly as described by Brown-Séquard in hemisection of the spinal cord. The patient was stabbed in the back of the neck, and as a result suffered from paralysis of the left arm and left leg. The reflexes were normal, but there was incontinence of urine. On the fourth week some slight power was returning to the left hand, and the next week to the left leg. In the seventh week he was able to walk awkwardly, there still being present a paresis and dragging of the leg. A year later, at the Pennsylvania Hospital Dispensary, he was found to have an excessive knee jerk and some ankle clonus in the paralysed leg. In the paretic arm the tendon reflexes were also exaggerated. As regards sensory alterations they closely conformed to Brown-Séquard's type—namely, hyperalgesia and tactile hyperæsthesia in the paralysed limb, anæsthesia and analgesia in the non-paralysed limb. Muscular sense and consciousness of position were lessened in the paralysed limb, but unaltered in the non-paralysed limb. Thermal sensibility was lost in the sound limb and increased in the paralysed limb. In surface temperature the paralysed leg was warmer. Similar differential conditions prevailed as regards the paralysed and non-paralysed arms, and the facts confirm the view of Brown-Séquard that the paths of tactile and painful sensibility decussate after entering the spinal cord.

(266) The Differential Diagnosis of Functional from Organic Hemiplegia.

Babinski (*Gazz. des Hôp*, May 5th and 8th, 1900) points out that in organic hemiplegia the paralysis is limited to one side of the body, while in hysterical hemiplegia it is not. This observation applies particularly to the face, the paralysis of which in the hysterical form is generally bilateral. In the organic form the paralysis is not systematic. If, for example, one side of the face is profoundly paralysed, the weakness remains quite evident during the bilaterally associated movement of the face, but in the functional the paralysis is usually systematic. For while the unilateral movements of the face may be completely abolished, the facial muscles on the paralysed side act well during the bilateral movemehts. In the organic there is muscular hypotonicity, principally at the beginning, which is shown in the upper limb by the exaggerated flexion of the forearm. In the functional form there is no hypotonicity; when there is, for example, facial asymmetry, it is due to spasm of the one side. The periosteal and tendon reactions are either abolished, diminished, or increased at the beginning in the organic, and later they are nearly always exaggerated with ankle clonus; but in the functional form these deep reflexes are unaltered, and there is no ankle clonus. In the organic hemiplegia the skin reflexes are generally altered; the abdominal and cremasteric are usually weakened or abolished; the movements of the toes on eliciting the plantar reflex is one of extension; in the functional hemiplegia the cutaneous reflexes are unaffected, and the plantar reflex is the normal flexor response. The character of the contracture in the organic paralysis could not be reproduced by a voluntary contraction of the muscles, while in the functional paralysis it well might. The evolution of the organic hemiplegia is regular; contracture follows flaccidity; improvement is progressive, and the paralysis does not fluctuate, now better, now worse. In the functional paralysis the evolution is capricious; the paralysis may remain indefinitely flaccid, or it may even be spasmodic at the beginning. The paralysis is variable in degree and in form, and there may be actual remissions.

(267) Larval Forms of Tabes.

Erb, of Heidelberg (*Münch. med. Woch.*, No. 29, 1900), refers to larval forms of tabes dorsalis, the diagnosis of which is difficult, and alludes to the fact that such forms may persist for years. The points of diagnostic value are (1) "lightning" pains, (2) slight paræsthesiæ, (3) diminished sexual power, (4) Romberg's symptoms, and (5) unilateral Argyll-Robertson's pupil. If to these symptoms be added the history of a previous syphilis, the diagnosis is made certain. The knee-jerk may or may not be absent; thus in 5 cases the knee-jerk was present, but the presence of the other signs confirmed the diagnosis. In one class of cases visceral crises (gastric, laryngeal, recto-vesical, etc.), appear early, and such cases may persist in the larval condition for a considerable time, or may develop into typical tabes dorsalis. For treatment mercurial inunction should be freely employed, and suspension may be regularly carried out by the use of suitable apparatus. The ultimate prognosis is, however, not favourable.

SURGERY.

(268) Suture of Wounds of the Heart.

Terrier and Reymond (*Rev. de Chir.*, October, 1900) publish a table of 11 instances of the suture of cardiac wounds collected from different sources. Death resulted in 8 of these cases, and the remaining 3 patients recovered. The fatal result was due in 2 cases to great loss of blood, and in 4 cases decided symptoms of infection were present. The authors in discussing the technical details of the surgical treatment of such lesions are of opinion that the best method of exposing the seat of injury in most instances is to form a thoracic flap, including with the soft parts the cartilages of the fourth, fifth, and sixth ribs, the hinge or attached portion of this flap being placed externally and away from the left margin of the sternum. Care should be taken after elevation of this flap to push the left pleura outwards, and not to cut into the pleural sac in exposing the pericardium. A continuous suture is preferred to an interrupted one in closing the cardiac wound. It is held advisable to close completely when possible, the wounds in the pericardium and pleura, and not to attempt drainage.

(269) Remote Results of the Radical Cure of Hernia.

Delbet (*Bull. et Mém de la Soc. de Chir.*, No. 28, 1900), who is attached to a "service des bandages," the function of which consists in the distribution of elastic stockings and trusses, publishes some statistics he has collected with the object of removing the uncertainty that at present exists with regard to the persistence of the results of the so-called radical cure of hernia. During the first six months of the present year trusses were applied in this "service" to 1,586 cases of hernia, 1,516 of which were inguinal hernias and the remaining 70 crural. Of the 1,516 inguinal hernias 1,509 had not been treated by any operation, and 7 only had recurred after operation. In the cases of crural hernia the proportion of failures was greater, as out of 70 instances of this variety there were 2 of return after operation. The author concludes that if the enormous number of operations performed for the radical cure of hernia in the Paris hospitals be taken into consideration, the small num-

ber of recurrent hernias observed in institutions for the supply of trusses is a sure indication that operations for the cure of this affection are really radical.

(270) The Etiology of Intestinal Hæmorrhage in Strangulated Hernia.

Kukula (*Ann. de la Soc. Belge de Chir.*, No. 7, 1899) by a study of an original case in Maydl's clinic and of 14 cases published by other authors, has been led to formulate the following conclusions with regard to the causation of intestinal hæmorrhage consecutive to reduction of strangulated hernia. Cases of such bleeding may be divided into two groups. In the first group, in which the discharge of blood occurs very soon after the reduction, this discharge may be caused by: (1) Contusion of the intestinal walls produced during taxis; by (2) temporary compression of the veins of the strangulated portion of intestine, or by venous thrombosis, such disturbances of the local venous system resulting in hæmorrhagic infarction of the intestine and mesentery and consecutive intestinal bleeding; or by (3) hæmorrhagic infarctions after very severe strangulation followed by complete ischæmia of the intestine. The hæmorrhage from the first is usually slight and indicated only by minute clots or by a black colour of the fæcal discharge. The hæmorrhage when abundant is in most instances due to the second cause. The association between intestinal bleeding and the third condition has not been clearly demonstrated. In the second group of cases in which the hæmorrhage is observed some time after the taxis or herniotomy, the discharge of blood is the result of exfoliation and ulceration of the mucous membrane of the strangulated portion of intestine. Such pathological change in the mucous membrane may be due to (1) Gangrene developed in consequence of complete intestinal ischæmia in a case of very acute and intense strangulation; to (2) necrosis caused by venous congestion either after violent strangulation of short duration, or after slight but prolonged strangulation; or to (3) necrosis of the mucous membrane due to venous thrombosis developed in consequence of compression, and involving more or less of the intestine.

(271) Tuberculosis of a Hernial Sac.

Faguet (*Prog. Méd.*, September 23rd, 1899) observes that this condition was recognised first by Cruveilhier in 1862. Joannesco reported 11 cases in 1891. The last published case (Nurdin's) appeared in 1897. Faguet's patient was an agricultural labourer, aged 18, previously healthy. In raising a heavy plough he felt a sharp pain in the left groin, and a rupture was discovered. Local colicky pains occurred. Seven months after the development of the hernia a reducible enterocele was detected; the testes and epididymis were healthy, but an indurated piece of tissue could be felt on the fundus of the sac. Radical cure of the hernia was performed. The intestine was healthy, so was the sac near its neck, but its fundus really consisted of tuberculous deposit of the diameter of a two-franc piece, and one-fifth of an inch thick. The deposit was uniformly nodulated, and not tuberous; indeed, its surface was regular. On microscopic examination, however, all the elements of tubercle were discovered. Six months later the patient entered the same hospital suffering from pulmonary and peritoneal tubercle, which proved fatal.

(272) Interstitial Inguinal Hernia.

Knott (*Annals of Surgery*, December, 1899) adds a recently observed instance of strangulated interstitial hernia to the scanty literature of this subject. The patient was a man aged 64, who made a good recovery from an operation performed within five hours after the first appearance of the symptoms of obstruction. This case, the author points out, illustrates the danger of herniæ of this kind when strangulation has occurred. Although the patient was submitted to operation after so short an interval, the gut was found in so bad a state that the propriety of returning it into the abdomen was for some time in question. It is asserted that in all cases of inguinal hernia presenting an unusual location or shape of the sac, great care should be exercised that a reduction of a portion of the contents of the sac into another compartment of the same be not mistaken for a complete reduction into the abdomen. The author believes that every case of properitoneal or interstitial hernia, even when not strangulated, should be subjected to operative treatment without delay. The application of a truss to a hernia of this kind is held to be unjustifiable.

MIDWIFERY AND DISEASES OF WOMEN.

(273) Treatment of Damaged Ureter in Abdominal Section.

Fenomenoff (*La Gynéc.*, October 15th, 1900) describes a very rough-and-ready way of dealing with a case of badly-damaged ureter, justified at least by success in this particular instance. He removed a pair of strongly-adherent broad ligament cysts. He feared that they were septic from suppuration, and therefore dissected very freely around their outer walls. In so doing he accidentally cut away a considerable segment of the right ureter. Hence neither suture of the two ends, nor even implantation of the proximal end into the bladder was possible. Fenomenoff, therefore, drew the ureter up out of the retro-peritoneal space, applied two ligatures as high up as possible, and then reduced the damaged duct. The patient made a complete recovery, without any renal symptoms save during the first week, when she felt lumbar pain, and the excretion of urine was below the normal. The corresponding kidney was somewhat enlarged. The patient was well in five weeks. Seven months later the patient reported that she still felt the pains, but there was no trouble with the urine. Experiments on animals have shown that sudden and permanent obstruction of the ureter causes atrophy of the kidney; this change must have occurred, Fenomenoff believes, in his own case.

(274) Spleen in Female Pelvis

Gouraud (*Bull. et Mém. de la Soc. Anat. de Paris*, May, 1900) describes this important anomaly, which he detected at the necropsy on a woman, aged 60, whose death was due to cancer of the pylorus. The long diameter of the spleen was horizontal, and it lay over the bladder and uterus. Its left side touched the pelvic wall, from which it was separated on the right by the sigmoid flexure, which turned to the right and covered the spleen. The peritoneum invested the spleen entirely, save superiorly to the left, where the organ adhered to the colon at a point where it received its vessels. The pedicle of the spleen was entirely retroperitoneal, and consisted of a dilated, tortuous splenic artery. The twists were produced by two fibrous cords, both vascular, probably containing the vasa brevia. One cord, retroperitoneal, passed towards the cardiac end of the stomach, the other, invested with serous membrane, passed to the inferior extremity of the kidney. There was no splenic vein. The pedicle ended behind the tail of the pancreas, which organ lay very obliquely, its tail being almost vertical. Along the posterior border of the pancreas ran a small vein in the position of the splenic and a tributary of the vena porta, but it arose at the tail of the pancreas, and had no connection with the spleen or its pedicle. The nature of the pedicle seemed to imply that the displacement of the spleen was congenital, but the twisting of the splenic artery looked as though the organ had descended from its original position; if so, however, the prolapse must have been very early.

(275) The Palliative Treatment of Inoperable Uterine Cancer.

Küstner (*Centralbl. f. Gynäk.*, April, 1900) says that one of the most trying symptoms of the advanced stages of uterine carcinoma is the offensive and penetrating odour which is evolved. In order to palliate this condition, he proposes to close the vulvar orifice, and by means of a vagino-rectal fistula divert the discharge into the rectum, where it may be more under the influence of the will, and hence regularly and effectively discharged. The operation employed consists of the following steps: (1) the removal of all necrosed tissue from the os by the thermo-cautery; (2) the application of a tampon (to which a thread is tied) impregnated with alcohol; (3) the formation of a recto-vaginal fistula and suturing of its edges with catgut; (4) thorough cleansing, vivifying, and joining together the vestibule and its walls by hair sutures. The tampon may be removed on the fourth day. The newly-formed fistula must be kept open, and any tendency towards obliteration obviated by dilatation. Should hæmorrhages occur, the vagina should be packed through the fistula, and the

usual water irrigations employed. The rectum and anus will need antiseptic attention in order to keep them clean and free from irritation.

(276) Cysts of Placenta.

De Jong (*Monats. f. Geburtsh. u. Gynäk.*, June, 1900) has carefully investigated this morbid condition and studied its literature. Placental cysts are either multiple or solitary, and vary greatly in size from microscopic proportions to a diameter of 4 inches. They lie on the fœtal aspect of the placenta in the basal part of the chorion. The cyst is developed by fusion of the ends of adjacent villi by fibrinous exudation after the atrophy of the syncytium. This exudation is probably secreted by the chorionic epiblast (Langhans's layer of epithelium). The inner wall of the cyst is lined with Langhans's cells, which hypertrophy and also break up and fall into the fluid contents of the cyst, their own secretion. A certain amount of hæmorrhage is observed in some placental cysts. The development of placental cysts seems to be a purely local change not due to inflammation or to any constitutional disorder. The obstetrician should therefore remember that even a number of large cysts in the placenta is of no clinical importance.

(277) Rupture of a Fœtal Sac into an Ovarian Cyst.

Urbain (*Gaz. Hebdom. de Méd. et de Chir.*, May 3rd, 1900) was consulted by a woman who believed that she had reached term. After exploration he diagnosed cyst of the right ovary and left extrauterine gestation. The patient was very ill, the legs œdematous, the belly enormously distended, its veins dilated, and its outline bilobular. The right lobe was the larger; it fluctuated. The left was firm and irregular in shape. The os uteri was patulous; the uterus measured over 4½ inches. At the operation a large ovarian cyst was emptied; it was multilocular, and in breaking down the septa the left tumour was found to communicate with one of the loculi. Urbain withdrew a macerated fœtus of the seventh month. Hæmorrhage was so severe that he at once packed both cystic cavities; the outer wall of the ovarian cyst was marsupialised. The placenta came away in fragments, and the patient was well in six weeks. On careful revision of the history of the pregnancy it transpired that during the seventh month the patient had an attack of abdominal pain and vomiting which lasted forty-eight hours. The fœtus doubtless entered the ovarian cyst at once.

THERAPEUTICS.

(278) The Treatment of Tetanus.

Moschrowitz (*Annals of Surgery*, October, 1900) in concluding an elaborate review of the modern treatment of tetanus, says that a rational treatment of this affection would have to include five important points. With regard to the first of these, recent researches indicate the necessity of destroying the bacteria at the seat of infection, and thereby preventing a further production of toxins. It is important to enlarge the wound, remove all foreign matter, and to destroy all organisms—saphrophytic germs as well as tetanus bacilli by actual antiseptics. It is necessary, in the second place, to endeavour to eliminate from the body the toxins already absorbed from the source of infection. The author basing his recommendation upon the theoretical ground that in experiments on animals the blood is nearly always found to contain the toxins, suggests that it may be well to perform venesection, withdraw a certain quantity of blood, and substituting for it normal saline solution. In dealing with the important point of neutralising and rendering innocuous the poison already absorbed by the injection of the serum of animals which have been rendered immune to the disease, the author gives no very decided opinion. The antitoxin treatment, he states, appears to have a distinctly beneficial influence on the course of tetanus, and the statistics he has collected show that with this treatment the mortality has been reduced from 90 to 40 per cent. The fourth question of immunising the body after local infection has taken place involves, it is pointed out, the injection of antitoxin as a prophylactic measure in all wounds when there is reason to suspect the possibility of the subsequent development of tetanus. By such treatment, it is asserted, an extensive epidemic of puerperal tetanus in a lying-in hospital at Prague was cut short, and numerous instances of good results from a similar course have been recorded in veterinary practice. Although the use of serum is a most important factor in the treatment of tetanus, the other recognised therapeutic measures, the author insists, should not be neglected. It is important to overcome the symptoms induced by the action of the toxins, and to calm the increased reflex irritability of the higher nerve centres by isolation of the patient and the free administration of narcotics.

(279) Formaldehyde as a Disinfectant.

Abba (*Centralbl. f. Bakt.*, Band xxviii, No. 12, 13) gives an important summary of the experimental results recently obtained with formaldehyde as a disinfectant for rooms. The controversy as to its value has lasted for several years, but careful researches have of late thrown much doubt on its practical utility. Abba states (1) that formaldehyde disinfects surfaces only when these are quite smooth or polished; (2) that it cannot be relied on when there is perceptible dust in the room; (3) floors, frames, ledges, cornices, etc., are not disinfected; (4) the surfaces of upholstered furniture are only rarely and not uniformly disinfected; (5) only smooth or polished walls are disinfected, and not reliably; (6) it is recognised on all hands that formaldehyde does not penetrate bedding; (7) disinfection with formaldehyde must be reinforced by sublimate and steam if it is to be thorough; (8) disinfection with formaldehyde requires at least ten hours for each room, necessitating special housing arrangements for poor people who come from infected rooms. As a rule, especially where ventilation is difficult, the rooms are not inhabitable for twenty-four hours; (9) the process is not cheaper than others; on account of the variability and inequality of its effects, it cannot be considered of practical utility as a disinfectant for general use.

(280) Toxic Symptoms following the use of Izal.

Hobday (*Journ. Comp. Path. and Therap.*, September, 1900) describes the toxicological effects following the application of a dressing of izal to the skin of dogs and cats. Being assured that as an external application it was absolutely harmless, he used it in the treatment of skin affections. But recollecting that a similar statement had been made in connection with creolin and its preparations, and that these had caused fatal results on several occasions, he used it with caution. From observations on dogs and cats he is convinced that izal, like creolin, is poisonous to them if used injudiciously. Its action is irritant and narcotic, and there is great necessity for caution in its use, particularly when it is applied to a large area of skin. In some instances the animal seemed to be well out of danger when paralysis of the hind limbs developed, and death ultimately ensued. Compared with creolin, its toxic action is not quite so rapid or so violent, but, as with that drug, it would be unwise to apply with friction to any large area of the body, in such a manner that it would be absorbed, a preparation containing more than 10 or 15 minims per pound of body weight. The first signs of danger are subnormal temperature, continual irritation, and involuntary muscular twitchings. These are followed by complete inability to rise, coma, and death.

(281) Treatment of Lupus by Unna's Method.

Krzysztalowicz (*Rev. de Thérap. Méd. Chir.*, 1900, p. 167) reports favourably on this method which consists in the combination of caustics and bactericides. For superficial cases the following formula is used: Salicylic acid, chloride of antimony aa 2 parts; creosote, extract of Indian hemp, aā 4 parts; adeps 8 parts. This is spread on the affected parts, covered with gutta-percha tissue, and kept in place for 24 to 48 hours. It is then replaced by simple boric vaseline for two or three days. The process is repeated till the granulation tissue begins to cicatrise. Deep cases of lupus are not much benefited by this application, and for these the following is substituted: Caustic potash, lime, green soap, distilled water: equal parts. In order to obtain a deep action, the paste must be moistened and covered with impermeable tissue. A tampon of damp wool is applied over the paste, and this is covered with pink aconite.

On mucous membranes the tampon is useless, because the mucous secretion moistens the paste. The scab separates after several days, and is replaced by granulation tissue. If there are deeper nodules left after the cauterisation they are treated by compresses of an aqueous solution of caustic potash, 1 in 5,000 to 1 in 10,000.

(282) Treatment of Gonorrhœa.

Garrow (*Montreal Med. Journ.*, February, 1900) considers abortive methods of no value unless cases are seen very early. His method of treatment is by copious irrigations with weak antiseptic solutions—bichloride of mercury and permanganate of potash used at a temperature of 115° F. to 120° F. Each irrigation is followed by an injection of protargol (⅛ to 2 per cent.) which is retained for 15 to 30 minutes. Irrigation should be begun at once, and repeated twice daily for four or five days; then daily for a week or more till the discharge is clear and the gonococci have disappeared. When the discharge is thin and serous the patient is ordered a mixed mineral and vegetable astringent injection. If the whole treatment is carried out by the patient the results are not so good. Alkaline diuretics combined with an anodyne are also recommended. Salol combined with cubebs helps to diminish the pus in the second week. The author does not recommend copaiba or sandal wood. In anterior urethritis when the morning drop and the "clap threads" persist there are always granular patches or inflamed follicles, which should be treated with nitrate of silver, followed by 25 to 40 per cent. boroglyceride. Posterior urethritis when acute should be treated with rest in bed, hot hip baths, leeches to the perineum, hot irrigations and injections of protargol. Tepid saline enemata and urinating in a hot bath are useful adjuncts. Salol and pulv. ipec. co. help to relieve vesical tenesmus. In chronic gonorrhœa irrigation with hot saline solutions followed by instillations of increasing strength of silver nitrate are useful. Local spots of inflammation can be treated by instillation by Ultzmann's syringe, after urethroscopic examination.

PATHOLOGY.

(283) Leucocytosis in Typhoid Fever.

Courmont and Barbaroux have made a series of observations on the changes both in number and character of the leucocytes in typhoid fever (*Arch. de Phys. et de Pathol. Gén.*, July, 1900). They state that there does not seem to be a fixed formula for the leucocytic condition in typhoid. Many different changes may be observed, so that in cases practically similar to the leucocytic curve may be quite different. In fact, two of their cases showing the greatest divergence in the behaviour of the leucocytes occurred in two patients, aged 33 and 35, both treated at the same time and in exactly the same way, and there being only a difference of one day in the duration of the two weeks; in one there was hypoleucocytosis, with decrease in the percentage of polynuclear cells; in the other there was hyperleucocytosis, with increase in the polynuclear percentage. In one the leucocytic curve rose during convalescence; in the other it fell. This shows the importance of not allowing the prognosis or diagnosis in typhoid to be too much influenced by the condition of the white cells. In some fatal cases hyperleucocytosis was present; while in others of a mild character the white cells were decreased. In the greatest number of cases, however, hypoleucocytosis was the rule. This may be temporary or constant. It is shorter in mild cases; more prolonged in severe. The authors are uncertain as to the exact period the decrease in leucocytes may be observed; their earliest case was on the seventh day. They also noted that frequently there is a rise in the leucocytic curve and the number of polynuclear cells towards the end of pyrexia or when the temperature begins to drop. As regards the polynuclear cells, as a rule they follow the leucocytic curve, but by no means constantly so. In the greater part of average cases, the percentage of polynuclear cells keeps high, notwithstanding that the total number of leucocytes diminishes. The writers therefore formulate the statement that hypoleucocytosis is due to decrease in the lymphocytes. The total number of polynuclear cells falls by proportionately much less, and their percentage is generally increased. In certain severe cases, however, the percentage of polynuclear cells is never raised above the normal, so much so that one might almost be tempted to give this fact some importance in prognosis were it not that this same condition is now and then observed in mild cases. One of the most constant observations is the considerable decrease of the leucocytes, especially polynuclear, during convalescence. It is not possible so far to define the relation of this with the gravity of the cases, nor to say how this phenomena is related to relapse. In cases of typhoid fever the leucocytic curve regains fairly rapidly its normal condition, though now and then the process is much prolonged. The reason of this is to seek. It is more especially the lymphocytes and mononuclear cells that first reach the normal. There may even be a temporary hyperleucocytosis, as a kind of reaction.

(284) Fat Embolism.

Ribbert (*Deut. med. Woch.*, June 28th, 1900) makes a further addition to his numerous contributions on this subject. He confirms his former discovery that multiple ecchymoses and fatty degeneration are common sequelæ when the emboli affect the brain and heart muscle respectively. The brain affections lead to definite symptoms, such as vertigo, etc., which do not come on for some days after the incident causing the embolism. Owing to the viscosity of the embolus, or more probably to the feebleness of the circulation, impaction occurs first in the lungs, and it is only if and when the embolus breaks up again that the systemic circulation is affected. An extensive fat embolism of the lungs may be seen within an hour of an injury, but even if it reaches into the capillaries from the first, which is not always the case, some time must elapse before any can be squeezed into the pulmonary veins. The author's further researches bear upon the source of the fat and arose out of an observation made by him of a case in which a man had a most extensive fat embolism without any fracture. This raised the possibility of the occurrence of this condition from simple concussion of the marrow. In the first place, it is not easy to understand the mechanism by which the fat would get into the vessels in the case of a fracture; the conditions of pressure would prevent the escape of more than the merest fraction of that found in an ordinary fat embolism. Secondly, if all the fat set free got into the circulation, it would not account for the amount actually occurring in a moderately extensive case, which Ribbert estimates at from 15 to 20 c.cm. Thirdly, very marked fat emboli may be seen in cases of trifling fractures—for example, of the skull and sternum, bones which contain very little fat, but injury of which is usually associated with extensive concussion of the whole body. The author hence concludes that not only is concussion of the bone marrow a far more important etiological factor than fracture, but that in every case of concussion of a fat-containing bone fat embolism results. He confirms these revolutionary views by experiments on rabbits, showing that the lesion can be produced by striking any of the long bones or by simply dropping the animal from a height on to the ground. He hence regards fracture of a bone as merely an associated phenomenon and of no more importance in respect of fat embolism than as an indication of concussion of the bone marrow.

(285) Elimination of Bacteria by the Liver and Kidneys.

Metin (*Ann. de l'Inst Past.*, June 25th, 1900) has conducted experiments to decide whether bacteria are eliminated in the bile and the urine, the opinions on this question being contradictory. Rabbits were intravenously injected with cultures of B. subtilis, staphylococcus aureus, B. anthracis, and other organisms, and guinea-pigs were inoculated subcutaneously with the same. Great care had to be taken to obtain the bile and urine unmixed with blood. These secretions were taken at periods from a quarter of an hour to twenty-six hours after inoculation, and in all cases where they were free from blood they were found sterile; B. anthracis causes hæmaturia and lesions in the kidney and urine taken twenty-four hours after inoculation gives cultures of the organism, but the bile is sterile. The kidneys and liver must therefore be considered impermeable to bacteria, unless the latter produce an admixture of blood with the secretion.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(286) Arterio-sclerosis.

J. W. Runsberg (*Finska Läkures Handlingar*, Bd. xliii, No. 8, 1900) says that, as regards the pathology of the condition, the heart is the principal seat of the sclerosis. The cardiac symptoms are, however, of somewhat contrary significance, one set arising from sclerosis of the coronary arteries, the other caused by disorganisation of heart functions consequent upon a general sclerosis in the arterial system. In the latter state there is cardiac hypertrophy; in the former myomalacia or myocarditis. Both conditions, however, may be present in the same patient, and the resultant symptoms be more or less mixed. There is also a sclerosis of the heart which commences in the aorta and semilunar valves. The arterio-sclerotic symptoms of other organs depend upon defective nutrition due to the degenerated state of the vessels (which weakness also may lead to ruptures of the cerebral arterioles), or to circulatory disturbances due to the heart hypertrophy. The author divides the scleroses in three classes: (1) Syphilitic sclerosis, attacking both small and large arteries, and characterised by intense local, without any general, trouble. (2) Arterio-capillary fibrosis, attacking the smaller and smallest arteries, characterised by important general circulatory disturbance. (3) Senile sclerosis, affecting all the arteries, and manifested by both general and local symptoms. It is not rare to meet with combinations of the three classes. The prognosis is bad, but in the syphilitic variety the process may be arrested by suitable early treatment. In all cases iodide of potassium is the only drug which appears to directly deal with the fibrosis. Prophylactics, in the shape of diet, alcoholic abstinence, exercise, and eliminatory measures should always have particular attention in likely subjects, and the condition of the heart regularly investigated. Angina, cardiac asthma, and other organic symptoms will require the usual remedies.

(287) Suprarenal Hæmorrhage.

Arnaud draws attention to some very interesting cases of hæmorrhage taking place into the suprarenals (*Arch. Gén. de Méd.*, July, 1900). In this paper he brings together some 80 observations. In more than half the cases, hæmorrhage into the suprarenals gave rise to no appreciable symptoms; in others it produced a voluminous hæmatoma, which in a certain few was quite palpable. The symptoms of this condition are at the best vague. As a rule, there are no true Addisonian manifestations, though occasionally there may be some bronzing and asthenia. It is pointed out, however, that, usually speaking, death follows too rapidly to allow such symptoms to be produced which requires more or less time. In other cases the symptoms are of a peritoneal character, and on *post-mortem* examination a considerable amount of post-peritoneal hæmorrhage is ascertained, with pressure on the abdominal organs. In other instances the symptoms are those of extreme nervous shock, characterised by almost sudden or rapid death, with occasionally delirium, convulsions, coma, subnormal temperature, and syncope. This latter group seems to contain the majority of cases. The shock, as may be gathered, is very severe, being evidently due to interference with the solar plexus. The term "suprarenal apoplexy" has been suggested, and the cases certainly possess distinctly apoplectic characteristics. The causation of suprarenal hæmorrhage is obscure. It seems to be chiefly due to lesions of the vessels of a degenerative character, or else chronic venous congesiion, under which condition the veins become greatly enlarged, and the whole capsule itself increases in size. Such enlarged veins are liable to become thrombosed with resulting hæmorrhage behind the block. In other cases, infective conditions and intoxications have a predisposing influence or are directly causal. The diagnosis of these cases, as will be seen, is extremely difficult, and it can only be by attention to every possible detail that one may surmise the presence of capsular hæmatoma.

(288) Actinomycosis of the Lungs.

Parascandolo (*Clin. Mod.*, November 7th, 1900), in a clinical lecture on the surgery of actinomycosis of the lung, summarises 14 recorded cases. The only 2 which recovered were those in which radical operations, with resection of four or five ribs, and cauterisation of the disease cavity in the lung were carried out. All those that were simply incised and drained ended fatally. The infection of the lung may be secondary to either cervico-facial or pharyngeo-œsophageal actinomycosis, or it may be primary, either through the bronchi or from an external wound. There are three forms clinically: (1) The pulmonary, with insidious onset, going on to induration of a large area of lung, generally in the subclavicular or postero-lateral regions, the apices being usually free; (2) the bronchial, with a diffuse bronchial catarrh, and fœtid muco-purulent expectoration, containing the fungus; (3) the pleural, with effusion: the coexistence of pleural effusion with retraction of some part of the thoracic parietes—due to fibrous changes in the lung—is pathognomonic. Another pathognomonic symptom is the presence of a swelling in the wall of the thorax where it has been invaded by the fungus, along with shrinking of the lung causing retraction of the thoracic walls; later on this softens and becomes subfluctuating without the formation of large abscesses. Puncture obtains a fluid containing fragments of fungus. Death may occur after months or years, according to the varying invasion of other organs by the disease; in one case of rapid diffusion of the fungus death occurred in twenty-four days.

SURGERY.

(289) Indications for Nephrectomy.

D'Antona (*Il Policlin.*, October 15th, 1900) in a paper on nephrectomy discusses the danger of leaving the patient with a single kidney. As a fact the recurrence of the disease in the other kidney is very rare, for the increased and more active circulation and the stronger current of liquid secreted protect it to some extent against suppuration, tubercle, or calculus. In truth, the healthy kidney, relieved from the presence of the diseased one, is less disposed to be attacked than it was before the operation. It is of course essential to be certain that the other kidney is really sound and acting well. D'Antona deprecates ureteral catheterisation; with the greatest care in disinfecting the bladder one cannot be certain that catheterisation may not infect the sound kidney; symptoms in case of infection are often insidious and delayed, and may not be attributed to their true cause. In many cases the diseased products occur intermittently in the urine, and even if the urine is normal but once in a given case it is enough to prove that there is one healthy kidney. The absence of this intermittence, however, has no diagnostic value. When the abnormal constituents are continuously secreted, so that there is doubt as to the functional integrity of one kidney, if the general condition of the patient is good, that in itself is enough to exclude a bilateral lesion. D'Antona tabulates 39 nephrectomies done by himself, with a mortality of 23 per cent. (only 16 per cent. among those done for pyonephrosis).

(290) Wound of Heart Successfully Treated by Suture.

Fontan (*Bull. et Mém. de la Soc. de Chir. de Paris*, May 15th, 1900) reports a case of wounding of the left ventricle and also of the left lung, in which free exposure of the injured organs and closing of the wounds by sutures resulted in complete cure. The patient was a soldier who came under the author's care in a very critical condition with six self-inflicted punctured wounds between the third and seventh ribs in the precordial region. There was a large collection of blood under the skin, and on percussion of the chest distinct signs both of pneumothorax and of hæmothorax could be made out. A large flap including the anterior portions of the fourth and two following ribs detached in front by dividing the costal cartilages, and loosened externally by section of the fourth and sixth ribs and fracture of the intermediate one, was turned outwards, and the large orifice thus made in the wall of the chest exposed the left pleural cavity containing a large quantity of blood, a superficial wound in the diaphragm, a wound of the anterior margin of the left

lung, and a third wound about 1 cm. in length in the pericardium. This last having been enlarged, a penetrating wound about 12 mm. in length was exposed on the anterior wall of the left ventricle. This last wound was closed by a continuous suture of catgut, and the cavity of the pericardium irrigated with boiled water. The wound in the lung was also closed by a similar suture, and the pleural cavity washed out. The patient made a good and speedy recovery, and when discharged after an interval of two months presented no signs of any bad results from his injuries. The author in his comments on this case states that the application of the suture to the wound in the left ventricle was attended with much difficulty due to the violent and extensive movements of the heart, which were caused mainly by the disordered action of the diaphragm set up by the sudden collapse of the left lung and the consequent disturbance of respiration.

(291) Transplantation of Thiersch's Grafts on the Inner Surface of the Larynx and Trachea.

Lénárt (*Pester medizinisch chirurgische Presse*, No. 19, 1900) points out the difficulty of preventing a serious degree of stenosis of the larynx and trachea after free removal of mucous membrane either by ulceration or by a surgical operation, and reports a case in which he practised with success Thiersch's method of skin transplantation with the object of covering a large surface denuded of mucous membrane during an operation for the removal of multiple papilloma, involving both the larynx and the upper part of the trachea. The extensive raw surface was covered by grafts taken from the left arm of the patient, which were kept in place by rolls of sterilised gauze. The incision in the larynx and trachea was left open for a time, and in the course of two weeks closed without the application of sutures. The operation for the removal of the growths was preceded by an inferior tracheotomy and the introduction of Trendelenburg's cannula. This cannula was removed at the end of the sixth week. At this time the interior of the larynx, examined by means of a mirror, was found to be slightly congested, but in other respects seemed quite normal. There was no disturbance of the relative positions of the vocal cords, and the inner surfaces of the air passage were quite smooth. The breathing was absolutely free, and the patient's voice, though somewhat muffled, was still distinctly audible.

(292) Wounds in Stomach Repaired by Transplanted Omentum.

Enderlen (*Deut. Zeit. f. Chirurg.*, April, 1900) has made some experiments in the interest of abdominal surgery, as not only has the omentum been sutured to a perforating gastric ulcer with success (Brann's case), but Senn has advocated transplantation of a severed piece of omentum for the repair of damage to the alimentary canal. W. H. Bennett successfully closed a large gastric ulcer by means of an omental plug. Turning to the pathology of injuries of the stomach, it is noted by Enderlen that small breaches in the mucous membrane from wounds, hæmorrhages, and caustics repair well, the glandular substance being restored. Enderlen made a series of experiments on cats and dogs. Portions of the wall of the stomach were excised. The surrounding mucous membrane always prolapsed freely. The piece of omentum, already fixed to the serous coat close to the seat of excision, was now sewn around the wound, the omental tisue being fixed to the serosa as before. A process of omentum was now sewn over the whole, being united by three or four sutures. This was necessary in the case of cats, where the omentum is very thin. The abdominal wound was now closed, and the animal was kept alive for a varying extent of time. The experiments proved not only that the transplantation succeeded, but that the omental tissue gradually assumed the character of gastric mucous membrane. Well-formed glands developed. This latter result is specially important and satisfactory when we remember that the gastric mucosa is a very important organ in itself.

(293) Suture of the Intestine for Perforation in Typhoid.

Bolton (An. Report Met. Asylums Bd., 1899, p. 189), after describing a case in which laparotomy was performed—though the life of the patient was not saved, yet there was no extension of the peritonitis after the operation—reviews the whole question of operation for perforated intestinal ulcers. If the operation is performed between twelve and twenty-four hours after the perforation there is the greatest chance of recovery. The chances are also greater if the perforation occurs at a late stage of the disease and if the case be mild. In regard to the operation, it is important not to waste time in searching for a second perforation. The aperture should be closed by invaginating a longitudinal strip of intestine by means of Lembert's or Halsted's sutures, after emptying the gut if it is loaded, and without paring the edges of the perforation. If the gut is badly ulcerated, the formation of an artificial anus is preferable to resection on account of the time saved and the less severe nature of the operation. The abdomen should be cleansed with saline or some mild antiseptic solution, and probably it is better to introduce a drainage tube than to stitch up the wound completely.

MIDWIFERY AND DISEASES OF WOMEN.

(294) Rupture of the Uterus.

Franz (*Monats. f. Geburts. und Gynäk.*, October, 1900) reports 12 cases of rupture in the Halle Maternity; 10 were complete and 2 incomplete. Out of the complete ruptures, 6 were transverse and anterior, 1 transverse and posterior, 2 longitudinal rents in the cervix extending into the uterus, and 1 transverse rent in the anterior vaginal fornix. Both the incomplete ruptures were longitudinal and in the cervix. The pelvis was narrow in 7 cases—6 head presentations and 1 cross-birth. There were also 2 cross-births without contracted pelvis; in the 3 remaining cases there was no mechanical obstruction. Of the 10 complete ruptures, 3 were due to violence. Franz adds the very important information that in 1 of the 3 the accident seems to have occurred after delivery during manual expression of the placenta. The symptoms of threatened rupture are not always prominent. Extreme tension of the cervix was only noted in 1 out of 4 cases where this condition was sought for by exploration, and in 1 of the 4 tension was quite absent. Out of the 10 complete ruptures, 9 were subjected to abdominal section; 1 admitted moribund, was plugged. In 4 of the 9 operations the child was delivered through the abdominal wound. In 4 panhysterectomy was performed, in 4 the rupture was sutured, in 1 supravaginal hysterectomy was preferred. Only 2 out of the 9 abdominal operations were saved—these were the panhysterectomies; 5 died from sepsis, 3 from bleeding (including the case where no operation was possible). Of the incomplete ruptures, 1 was treated with the tampon and died of sepsis, 1 underwent supravaginal amputation and died of hæmorrhage. All cases of rupture of the uterus should be treated as though already septic, for, though some are attended before infection has set in, this fact cannot be proved in actual practice. Hæmorrhage and sepsis are the two dangers and they are best met by total hysterectomy. He prefers the vaginal route. Franz admits that all cases of rupture do not demand operation. In every case, even when the rupture is complete, conservative treatment must first be considered.

(295) Cancer of the Body of the Uterus.

Calderini (*Ann. de Gynéc. et d'Obstét.*, September and October, 1900), out of 150 cases of uterine cancer under his care, observed 8 where the cervix was quite healthy. Diagnosis was always made by scrapings, and vaginal hysterectomy was recommended in all; 6 patients consented; 3 have recovered, and the disease has not recurred. In the first the operation was performed in 1891, in the second in 1892, and in the third in 1893. The first patient was 38 when operated upon; she had been subject for three years to hæmorrhage, and recently the discharge had become fœtid. The second was 46; she suffered when 45 years old from amenorrhœa for twelve months, followed by fœtid mucous discharge for four months. The curette brought away fragments which showed adenoma becoming malignant. The third patient was 59, and four years after the menopause (which seemed delayed till 55) a show came on about once a fortnight, lasting for a year and a-half, when the operation was done. Thus, though cancer of the body is rare, it is by no means unknown, and fungous

endometritis must always be looked upon with suspicion. Calderini insists that when this affection is diagnosed by the curette in an elderly patient the uterus should be removed at once, as it is exceedingly prone to degenerate into adeno-carcinoma of the body. By acting on this principle there will be no fear of recurrence or of operating when it is clear, on the evidence of what is discovered during the hysterectomy, that the disease has advanced beyond the limits of the uterus.

(296) Abdominal Hysterectomy for Cancer.

König (*Centralbl. f. Gynäk.*, No. 43, 1900) finds that the more favourable the immediate results of vaginal hysterectomy the less satisfactory were the after-histories. He preferred abdominal hysterectomy after Freund's method, which he had practised in seven cases, with three deaths. This high mortality was due to the fact that all cases were too advanced to allow of the vaginal operation. Peiser's practice was adopted; that is to say, that the pelvic cellular tissue was carefully cleared—before the removal of the uterus—of glands, lymphatic vessels in connection with the genitals, and plain muscle fibres. The operation was long lasting, from two and a-half to three hours, but very little blood was lost. Preventive ligature of the hypogastric artery is unnecessary and useless, as the collateral circulation is too freely established. As much as possible of the pelvic peritoneum should be saved. Thorough isolation of the ureters is of high importance, and can be done without catheterism of those ducts. On the morning of the operation the cancerous tissue is thoroughly scraped out and cauterised, and just before the abdomen is opened the cavity made by the scraping is once more cauterised and the vagina thoroughly disinfected.

(297) Pregnancy and Fibroid in Uterus Unicornis.

Kehrer (*Das Nebenhorn des dippleten Uterus*, Heidelberg, 1900) has prepared an important monograph on uterus unicornis, including uterus bicornis with one horn obstructed. He reports 82 cases from recent medical literature, including one under his own observation. The patient was 28 and had borne three children. She had exceeded term for three weeks. Pregnancy in right rudimentary cornu being diagnosed, it was amputated, and the patient again became pregnant. He divides these malformations into two varieties connected by intermediate forms: (1) Uterus bicornis and septus bilocularis with relatively good development of the musculature and vessels of the more or less atresic, gravid, rudimentary cornu. Here that cornu undergoes almost normal evolution. Rupture is rare till the seventh month, and as a rule pregnancy continues till beyond term. The pedicle is usually thick, it may contain a very narrow cervical canal. (2) Uterus bicornis and septus bilocularis, with very ill-developed rudimentary cornu. Evolution is here very imperfect, so that rupture within the first six months is almost certain. The pedicle is constant, and usually solid, seldom bearing a trace of a canal. As to prognosis, Kehrer finds that most cases rupture within the first six months, in some the fœtus, dead before or at term, is retained, whilst some undergo operation. Twelve cases of hæmatometra in this variety are recorded; the distended cornu was never larger than a goose's egg. In 5 there was hæmatosalpinx as well. In 1 only the hæmatometra ruptured, apparently between the layers of the broad liga- When a trace of a cervical canal, patent throughout, exists, conception in the ordinary way is always possible. When the pedicle is quite solid, the sperm cell may fertilise an ovum in the opposite ovary (transmigratio ovuli et seminis externa, seu intraperitonealis), or may get over to the ovary attached to the rudimentary cornu and fertilise an ovum on that side (transmigratio seminis externa seu intraperitonealis). The pedicle was solid in 78 per cent. of all Kehrer's cases. The right or left cornu were involved with almost equal frequency. Rupture is most frequent in the fourth month (47 6 per cent.), as the gravid cornu has begun to rise above the protecting bony pelvis. The normally developed horn ceases to menstruate, as a rule, hypertrophies, and develops a decidua which may be cast long before the death of the fœtus. Cornual pregnancy is rarely painful at first, as is the case with tubal pregnancy; rupture is often sudden and is very fatal. In 23 out of the 82 cases where rupture did not occur, the fœtus died before, at, or after term, its death usually being preceded by labour pains and active fœtal movements. A cachectic condition follows. The results of operation are favourable: 45 out of the 82 cases underwent abdominal section, 39 recovered (86.7 per cent.), 7 bore children again afterwards; 2 of the 6 deaths were due to loss of blood before the operation, 4 were from peritonitis, 1 of the cases being clearly septic beforehand.—Heinricius (*Monats. f. Geb. u. Gynäk.*, October, 1900) reports a case of myoma in each cornu of a rudimentary uterus bicornis unicollis. In 1891, when the patient was 31, she was first examined; she was married, but the period had never appeared, though smart pains set in about every two or three weeks. Sexual intercourse was attended with occasional pain, but it was somewhat pleasurable, except during the pseudo-period. The vagina was about an inch deep. Uterus rudimentarius was diagnosed. The breasts were well developed, the pubic hair thick, and the external organs normal. In 1897 the same patient came again under Heinricius's care. A firm, movable tumour filled the lower part of the abdomen; on pelvic exploration, a second tumour as big as a fist was detected. At the operation, the tumours were found to be myomata, each in one undeveloped cornu, each bearing a rudimentary uterine cavity with endometrium, and each had a round ligament and Fallopian tube proceeding from it. There was a rudimentary cervix of the size of a pea. Both ovaries were present. Convalescence was rapid. The blind sac representing the vagina did not communicate with the cervix. The same authority (*ibid.*) reports a case of ovarian tumour, hæmatometra, and hæmatocolpos in uterus bicornis, unicollis rudimentarius, and vagina rudimentaria. The patient was a girl, aged 21; she had never menstruated, but was subject to pains and vomiting about every third week ever since she was 15. The breasts, pubic hair, and vulva were well-developed. The vagina was entirely absent, and the tissue between the rectum and urethra very thin. There was a tumour as big as a fist, pressing on the rectal wall, and almost fixed, and another, movable and reaching above the pubes. The operation was complicated, and the bladder and urethra were damaged. There was a cystic tumour of the left ovary, which was removed with its tube. This tube and the round ligament were connected with a left uterine horn full of blood, which extended into a blind vagina. The right tube and ovary were normal, the tube and round ligament sprang from a small nodule representing the right cornu. As an artificial vagina was made and the right ovary not removed, the period came on, though irregularly, after convalescence.—Gunsett (*Hegar's Beiträge*, Vol. iii, March 3rd, 1900) reports 3 cases of myoma in double uterus. (1) Multipara, aged 40, menorrhagia and tumour. There was a fibroid in the right cornu, partly interligamentary. The uterus is classified as "duplex bicornis cum vagina septa," and the left uterus with its appendages were left untouched. It is not stated if the myomatous cornu were perfect. (2) Multipara, aged 28. Amputation of the whole mass supravaginally was performed, and reported as "uterus bicornis unicollis, with myoma of the inner wall and the septum." (3) Multipara, aged 46. Amputation as in second case. "Uterus duplex myomatosis." A large myoma in the right cornu; in the left were two interstitial fibroids, and a large growth of the same kind lay in the septum, between the cornua.—Freund (*ibid.*), in a monograph on the relation of abnormal growth of hair associated with malformations, reports one case where a woman, aged 22, was in her first pregnancy; there was hair on the face, breasts, back, abdomen, and thighs. The uterus was of the septus bicornis type, and abortion was induced. The second case was in a bearded woman, a multipara, aged 42. She had a patulous urachus, a long vermiform appendix, and a deep post-anal dimple. The uterus is described as unicornis.

THERAPEUTICS.

(298) The Light Treatment in Rodent Ulcer.

Valdemar Bie (*Dermat. Zeit.*, vol. vii, August, 1900, Part 4, p. 630) contributes a paper on the treatment of epithelioma

of the skin (ulcus rodens) by means of concentrated light. Finsen brought 16 cases before the Copenhagen Dermatological Society. In 3 the results had been *nil*: 5 patients were improved, but not cured; 7 were cured, at any rate no recurrence had up to the time been noted. One patient, apparently cured, had had a recurrence. One of the 3 unsuccessful cases, with a palm-sized rodent, had had 89 sittings, but the case from the description was evidently a bad one. Why the 2 others had not improved (81 sittings in one, number not stated in the other) could not be explained. Among the patients who had been improved the rodent was situated on the eyelids in two, hence the treatment had to be carried out gingerly and unsatisfactorily for fear of injuring the sight. There has been no recurrence in the 7 cases reckoned as cured for 2½ years, 11, 11, 9½, and 6 months (latter lapse of time in 3 cases). Whether the cure is certain in these cannot be positively asserted. In these patients, too, the disease was superficial and limited in extent, and therefore very suitable for the light treatment. In all the cases a microscopical examination was carried out, definitely showing the disease was a rodent ulcer. In one or two cases it was apparently epitheliomatous (that is, rapidly-growing cancer of the skin in contradistinction to rodent ulcer). One growth is noted as (microscopically) carcinoma (scirrhus), and affected the lip. This patient's condition was first treated under the impression that it was lupus vulgaris. He was improved, but after microscopical examination it proved to be cancer of the lip, and he was sent to hospital for surgical treatment. In connection with the effects of the light rays on the living organism, the following are of some interest: Finsen, examining the tail of a tadpole after an exposure of 10 to 15 minutes to the chemical rays, observed that the circulation in the smaller capillaries became slower, terminating in complete stasis, with diapedesis of the white corpuscles. A few red blood corpuscles were also extruded. Magnus Möller, of Stockholm, has confirmed this by his microscopical investigations of normal human and rabbit skin subjected to weak electric rays (Möller, Influence of Light on the Skin in Health and Disease, *Bibliotheca Medica*, Abth. D. ii, Heft 8, 1900).

(299) Subarachnoid Cocainisation.

This method of producing anæsthesia in the lower portion of the body is now being much used even in private practice, and various modifications are gradually introduced to overcome difficulties of technique. Fowler (*New York Med. Journal*, October 20th) describes a combined aspiration and injection instrument for the purpose. It consists of a double needle, one passing within the other. The inner one is of steel, and projects beyond the outer platinum one. This enables a very fine point to enter the spinal canal, and only necessitates the withdrawal of the inner needle if any clot, etc., occludes the lumen, thus avoiding a second puncture. The inner needle is secured to the outer one by a bayonet lock. A glass bulb is arranged to receive the cerebro-spinal fluid as it exudes, and there is a small aspirating bulb by means of which a vacuum can be maintained until the needle has been partially introduced, and any blood aspirated from the lumen. Massey (in the same number) reports from his private practice a case of hæmorrhoids in which he used this method of anæsthesia, and points out that many persons have a special idiosyncrasy for cocaine, hence care should be taken to adopt the dosage to the individual, and the solution should be used as weak as possible. In his case, 30 minims of a ½ per cent. solution produced total anæsthesia for five hours, but the operation was fully concluded within an hour and a half, so that probably 15 minims would have sufficed. Goffe (*Medical News*, October 13th) used the injection in a case of abdominal hysterectomy, in which the analgesis was complete and the results gratifying.

(300) Lumbar Puncture.

Hand (*Amer. Journ. Med. Sci.*, October, 1900) gives a summary of what is known as to the value of lumbar puncture, which was first introduced by Quincke in 1891 for the relief of excessive intracranial pressure in hydrocephalus. The causes of increased tension in the cerebro-spinal fluid are: Inflammation of the internal or external membranes, including hydrocephalus; tumours, chlorosis, traumatism, toxic states, such as are produced by lead, uræmia, or the infectious fevers. Pfaundler has shown that the normal subarachnoid pressure in the sitting position is 20 to 25 mm. of mercury, about half of which is hydrostatic and disappears when the patient lies down. A sterilised trocar should be introduced 5 to 10 mm. to one side of the middle line between the third and fourth lumbar vetebræ and passed for 2 cm. in children, or for 4 to 6 cm. in adults, slightly inwards, and in older children and adults upwards, until the sense of touch determines when the cavity is reached. As an aid to diagnosis the method has a wider field than as a therapeutic agent. The fluid drawn off may vary chemically and physically. Thus the glucose it contains, which normally amounts to 4 or 5 centigrams per 100, is increased in pneumonia and is absent in the later stages of tuberculous meningitis and in the whole course of meningitis caused by Weichselbaum's meningococcus or Fraenkel's diplococcus. The normal amount of albumen, which is about 0·2 per mille, is increased in inflammation and some cases of tumour or apoplexy. In meningitis it is commonly 2 to 3 per mille, and in purulent meningitis as much as 7 to 9 per mille. Turbidity speaks for meningitis, though in tuberculous meningitis the fluid may be almost clear. Fibrin always forms in meningitis when the fluid is allowed to stand, but never does so in cerebral tumour. Blood in the fluid is usually due to puncture of a blood vessel by the needle, but is also met with in injuries to the head or spine, subdural hæmorrhages, or apoplexy into the ventricles, and occasionally in meningitis. Staphylococci, streptococci, pneumococci, meningococci, typhoid bacilli (in two cases), bacterium coli, and tubercle bacilli, have all been found in the fluid. The last-named organism may be demonstrated by injecting the fluid into a guinea-pig, or by allowing the fluid to stand for some hours, fishing out the slight net of fibrin which forms at the bottom with a platinum needle, fixing it on a cover-slip and staining. It is not safe to draw conclusions from negative bacteriological results. Therapeutically, lumbar puncture is of value in epidemic cerebro-spinal meningitis, and if frequently repeated may bring about recovery, partly by evacuating the pus from the subarachnoid space. In tuberculous meningitis it is only palliative, temporarily lessening headache and contractures. In cases of cerebral tumours with a high intra-arachnoid pressure, lumbar puncture has frequently been followed by sudden death, either because the tumour blocks the Sylvian aqueduct or because the withdrawal of fluid from the spinal subarachnoid space allows the tumour to sink towards the foramen magnum and press on the vital centres. In chronic hydrocephalus lumbar puncture may accomplish as much as ventricular aspiration. In apoplexy, hæmorrhagic pachymeningitis, cerebral softening, and embolism its use is dangerous and useless. Lumbar puncture has also been used with apparent success in uræmia, lead encephalophy with coma, chlorosis, infectious diseases with cerebral symptoms, and in spinal injuries with paraplegia.

PATHOLOGY.

(301) Pathology of Plague.

In addition to cases of primary pneumonic plague, in a certain number of bubonic cases there are pulmonary complications and signs of broncho-pneumonia. The sputum in these cases contains the bacillus in greater or lesser quantity, and its presence is easily demonstrated by inoculation into animals. Metin (*Ann. de l'Inst. Pasteur*, September 25th, 1900) has conducted a series of experiments to discover how long the bacilli remain present in the sputum, and whether they are virulent during convalescence. He found that by the eighth day of apyrexia the virulence of such bacilli as were present was attenuated, and that on the tenth day the sputum was inoffensive in all cases examined. Metin also studied by experiment the properties of the serum of individuals convalescent from plague. He found that in the case of guinea-pigs it exhibits properties preventive and even curative. Similar experiments on mice, when the serum was three months older, were negative in result.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(302) The Toxic Dyscrasia of Diabetes.

Lépine (*Sem. Méd.*, November 21st, 1900) discusses the toxic symptoms of diabetes. A diabetic urine contains not only acetone and diacetic acid, but also, especially when toxic symptoms are present, β-oxybutyric acid, and an increased proportion of ammonia. Acetone and diacetic acid are not strong enough poisons to account for the symptoms; β oxybutyric acid has no marked toxicity when given in large quantities to a dog whose pancreas has been removed; so that a slow acid infiltration of the tissues has lately been regarded as the cause of the toxic phenomena. This, however, does not explain certain symptoms which precede the origin of coma—for example, acceleration of pulse and dyspnœa. Moreover, the inefficacy of alkaline medication points to an additional causative factor. Now, β-amido-butyric acid, given experimentally to a dog or cat, causes acceleration of pulse, increased amplitude of respiration, and coma. This acid has not been found in the urine or organs, but may still be an intermediate product during the formation of β-oxybutyric acid from proteid matter, an origin which is probable in addition to that from fat. β amido-butyric acid on hydration gives rise to β-oxybutyric acid and ammonia, and is itself an hydration product of nitrile amido-butyrate, which is practically innocuous. Such reactions would account for the increase of ammonia in the urine at the onset of toxic symptoms, and indicate a rational line of treatment. If the foregoing explanation be true, it may well be possible, by means of a phenol, to carboxylise the poison in the tissues, and so produce a harmless nitrile body in its stead. Treatment by phenols has not so far been very successful, but is worth trial. In the absence of further investigation, however, Lépine advises reliance upon the recognised measures: (1) Alkaline medication; (2) the intravenous injection of salines, (3) inhalation of oxygen.

(303) Diphtheria of the Digestive Tract.

Schoedel (*Münch. med. Woch.*, June 26th, 1900) in a case of diphtheria, found *post mortem* a large patch of membrane in the stomach, in which the bacillus was present in pure culture. There were also signs of enteritis in the duodenum, ileum and colon. This led him to investigate other cases as to the presence of the organism in the digestive tract, with the result that in two cases of faucial disease the bacillus was found in pure culture in the stomach, and in another case where enteritis was present it was found in the lower ileum. In 8 cases the fæces were analysed bacteriologically with negative result, except that a single specimen was thought to have been observed in one culture. No negative observations in regard to the stomach and intestine are given by the author. He believes that under ordinary circumstances the hydrochloric acid of the gastric juice is able to deal with such bacteria as gain entrance to the stomach, but that in a severe attack, where this secretion is interfered with, a local diphtherial process may be set up and also attack the intestine.

(304) Aphasia Complicating Infectious Diseases in Children.

Inschitta (*Gazz. degli Osped.*, June 17th, 1900) draws attention to the occurrence of aphasia in children during or after an attack of one or other of the infectious diseases—for example, measles, scarlet fever, typhoid, pneumonia, etc. The mode of action is probably a toxic poisoning by the toxins of the specific disease, causing very minute and more or less temporary changes in the speech centre. Occasionally the aphasia may be embolic; for example, as a result of detachment of an embolus in the course of an endocarditis. The prognosis, as far as life is concerned, is good, and most of the cases recover as far as function is concerned, although in post-diphtherial aphasia the outlook is not so good. In the aphasia which sometimes occurs in the course of tuberculosis the prognosis is always bad. The relative frequency of aphasia in certain of the exanthemata is given as scarlet fever, measles, and variola, in the order named.

(305) The Earliest Symptoms of Multiple Neuritis.

Popoff (*Neurol. Centralbl.*, No. 13, 1900) states that the general belief that paræsthesiæ and pareses are the earliest symptoms in patients suffering from multiple neuritis is only partially correct. It is now possible by the use of electrical methods to detect even earlier changes in muscles and nerves. Thus in alcoholic patients, before the onset of polyneuritis, it is possible in some cases to show that the interossei muscles of the hand do not contract to faradic stimulation, while the response to galvanic stimulation is diminished. In an elderly alcoholic patient, aged 68, and the subject of an old left-sided hemiplegia, there were present ataxia in the legs, pain in the calves, and Romberg's symptom. Electrical testing showed a diminished reaction to faradic stimulation in the left foot (muscles of the toes) and left hand (fingers). These indicated a commencing peripheral neuritis, which subsequently grew more pronounced. In another patient, a man, aged 40 years, and a sufferer from lead poisoning, there was hemiparesis and loss of cutaneous tactile sensibility on left side. The thenar muscles of the right hand and thenar interossei muscles of the left hand reacted feebly to the electric (faradic) current, and at a later stage distinct symptoms of polyneuritis appeared. The absence of response to faradic stimulation and the diminution of response to the galvanic in the peripheral muscles are thus valuable diagnostic signs as the earliest indications of polyneuritis.

(306) Solitary Adenoma of the Liver.

Barbacci (*La Clin. Mod.*, an. 6, No. 38) reports the case of a man, aged 50, who died of cardiac mischief, and in whose liver was found *post mortem* a small solitary adenoma. No symptoms had been present during life. The author has collected 11 similar cases, and a study of these shows the following characteristics of this class of tumour. When discovered it has always been by accident, so that it is obvious they give rise to no symptoms; they are about equally divided as to sex; may affect any age from 2 to 69 years, and any part of the liver; as a rule, the surrounding liver tissue is unaffected. In shape they are rounded, and vary from yellowish to greenish white. They are clearly marked off from the liver substance by a capsule, from which they can easily be enucleated. Structurally, they are formed of cells, which present the fundamental morphological characters of hepatic cells. They are absolutely benign, and probably congenital in origin.

SURGERY.

(307) Urethral Fistula.

Unterberger (*Monats. f. Geburt. u. Gynäk.*, March, 1900) and Jahn (*Beit. zur klin. Chirurg.*, vol. xxvi, part 2, 1900) have published two memoirs on this subject, as important as the collection of papers on urachal cysts noted last year (Epitome, vol. i, 1899, par. 510). In the original case published by Unterberger the symptoms of fistula developed through obstruction to the bladder caused by retroversion and partial incarceration of the gravid uterus. The patient, aged 23, was sent into hospital as a case of "ovarian cyst ruptured through the umbilicus." A clear yellow fluid had run away from the navel for three weeks. A cystic tumour extended as high as the umbilicus; a tense, elastic swelling filled the pelvis, pressing down very low; the cervix could not be reached; the vagina showed the violaceous discoloration of pregnancy; an aperture, very minute, was detected in the umbilical cervix, and fluid which proved to be urine flowed from it. For a fortnight no urine had passed by the urethra. Into that canal Unterberger passed a long curved metallic catheter. Nearly two pints of urine came away mixed with pus, the cystic tumour disappearing, and urine ceased to flow through the navel. The pelvis was still filled with the elastic mass. The patient was kept at rest and carefully catheterised, the umbilicus became dry as no more urine escaped from it, and at the end of about three weeks the uterus reduced itself. The sound was passed for diagnostic purposes; next day contractions set in, and four days afterwards the patient was delivered of a five months child. A fortnight after

labour the uterus was found retroverted and retroflexed. The original displacement was traced to a fall ten feet on to a floor during the first month of the same pregnancy. On discharge, two months after delivery, the catheter could be passed almost to the umbilicus. The urine was clear and passed voluntarily without pain. In the original case which forms the basis of Jahn's paper, the patient was a boy, aged 5. Shortly after birth his parents noticed that but little urine passed from the urethra, but quantities of fluid escaped from the navel. When 5 years old a right inguinal hernia developed, then further attention was directed to the older trouble. The umbilicus was flat and nearly as big as a shilling. It bore a funnel-shaped depression, whence urine issued when the abdominal muscles were set in action. A catheter of about one-fifth of an inch diameter passed easily for over 5 inches downwards in the direction of the symphysis. Another catheter, after passing with ease through the urethra into the bladder, touched the former passed from above. On applying pressure to the umbilicus urine could be passed, though in a weak stream, through the urethra. The parts were examined by the cystoscope passed from above. Von Mikulicz operated. He dissected away the umbilicus and the walls of the urachus, which widened greatly towards the bladder. The peritoneum was opened at one point and closed. Finally, the urachus was cut away at its vesical attachment, and the transverse wound in the bladder closed by suture. The lower end of the wound over the sutured bladder was drained with iodoform gauze. About two months later three attacks of fever occurred without any cause being manifest; micturition was normal. Three years and a-half after the operation the child, now 8½ years old, was in very good health. The urine was passed in a full stream, and was normal.

(308) Etiology and Pathogenesis of Appendicitis.

KLECKIEGO (*Przeglad Chirurgiczny*, iv, 586, 1900) has investigated experimentally the causation of appendicitis, and finds that the chief cause resides in the infection of the appendix vermiformis or in the action of the products of the micro-organisms which invade this organ. It is not yet known which of the intestinal microbes is the chief agent in appendicitis. In artificially-produced appendicitis in the rabbit the author has noted an increase in the virulence of the bacterium coli commune. Further, experiments by Kleckiego show that (in the rabbit) appendicitis may also be determined by diminished resistance in the organ. The infection is always secondary to factors which act indirectly by creating a morbid predisposition or by acting in an accidental fashion. In this category must be placed certain anatomical peculiarities of the appendix (excess of length, deformity, displacement), mucomembranous enteritis, scybala, foreign bodies, etc. The many pathogenic theories of appendicitis all emphasise this or that secondary factor, neglecting all the others; under this heading come the "appendicular colic" theory of Talamon, and the "closed cavity" theory of Dieulafoy.

(309) Intestinal Obstruction from Gall Stone.

MORESTIN (*Bull. et Mém. de la Soc. Anat. de Paris*, February, 1900) reports this condition in a woman aged 82, admitted into hospital five days after the beginning of an attack of vomiting and abdominal pain, which had never ceased. Neither fæces nor flatus passed, and the vomiting was becoming fæcal. The parietes were fat, the abdomen chiefly distended in its middle part, and tender in the umbilical region, no tumour could be felt, and resonance was universal. At the operation much red serum escaped from the peritoneal cavity; the obstruction was detected over 19 inches above the ileo-cæcal valve. A foreign body could be felt through the walls of the gut; its yellowish-white colour and its facets showed through the intestinal tissues. This body, a calculus, was readily extracted by an incision an inch in length, made along the convex border of the intestine. The intestinal walls were united in two layers. The operation was over in a few minutes, but the patient never rallied, and died in three hours. The large intestine, especially the sigmoid flexure, was full of hernial diverticular pouches, each containing an oval pellet of hard fæces. There was an adhesion between the gall bladder and the duodenum at the junction of its first and second part, and the walls of the adherent structures had yielded; the fistulous communication, through which the calculus had passed, was wide enough to admit a finger. The cavity of the gall bladder was capacious enough to lodge a pigeon's egg, and contained one faceted calculus as big as a cob nut. The gall stone which had caused the obstruction was as big as a large chestnut, and weighed over a quarter of an ounce.

(310) Carcinoma of the Appendix Vermiformis.

HURDON (*Johns Hopkins Hosp. Bull.*, July-August, 1900) describes a case of primary and a case of secondary carcinoma of the appendix. The first was discovered in the course of an operation for retroflexion of the uterus. The appendix was in the pelvis and enveloped in dense vascular adhesions. The distal end was distended, but in the middle third the lumen was almost obliterated by firm new growth; a concretion was present. The new growth was found to consist of epithelial proliferation and infiltration in the form of nests and cylindrical processes, originating in the Lieberkühn's glands. Only three cases of carcinoma of the appendix have been reported in which a microscopical examination was made—one in a woman of 50 who died of heart disease closely resembling the one here recorded; in the other two the disease involved the cæcum secondarily, and communicated with the surface of the abdomen by sinuses. A case has been recorded by Gifford, where a sarcomatous growth surrounded a concretion in the appendix. The case of secondary carcinoma was discovered during an operation for ovarian carcinoma; there was also a growth at the pylorus, and the surfaces of the broad ligament were studded with small nodules. The muscular and submucous layers of the appendix were infiltrated with new growth, the outer third was distended and contained a concretion.

(311) Treatment of Strabismus in Young Children.

PRIESTLEY SMITH (International Congress, Utrecht, 1899) advocates the treatment of strabismus in early infancy—in fact, from its inception. In this way loss of power of fixation in the squinting eye may be avoided. Our means of treatment are, broadly speaking, three. First, we can diminish accommodative effort and sharpen vision by glasses, or we can hold accommodation in abeyance by the continued use of atropine. Secondly, we can exercise the squinting eye, or both eyes alternately, by the use of a pad or shade. Thirdly, we can operate. If no improvement results from steady persistence in the use of glasses and the pad, he resorts to early tenotomy, as he thinks the chance of getting binocular vision is thereby much increased. He has operated several times at 2 years of age, and more frequently at 3 and 4, and has seen no reason to regret it. He urges that in every case the child should be thoroughly examined soon after the squint begins, and that the profession, and through them the public, should have this principle impressed upon them.

MIDWIFERY AND DISEASES OF WOMEN.

(312) Malignant Adenoma.

SELBERG (*Virchow's Archiv*, Bd. clx, Hft. 3, 1900) has had the opportunity of examining a large number of preparations which microscopically were true adenomata, but the clinical history of which was that of carcinoma. There is a considerable difference of opinion amongst authors as to whether the malignant adenomata should be considered a distinct group of new growths. The malignant adenomata of the uterus have provided most of the literature of the subject; Schröder was the first to give an accurate description of these growths, and divided them up into adenoma diffusum and adenoma polyposum. Most authors have followed him in distinguishing the disease from carcinoma; but Kaufmann has maintained, on the ground of a single specimen, of a growth originating in a cervical stump left after supravaginal amputation, that there is no distinction between the two. The author describes two specimens of cervical adenoma and three of adenoma of the body of the uterus clinically malignant, but consisting entirely of glandular proliferation—that is, spaces

lined with epithelium resting on a fibro-muscular framework. The cells are all of the one type; there is not the polymorphism of cancer cells, nor are the solid masses or columns of cells characteristic of the latter disease found in the malignant adenoma. Five cases of malignant growth of the digestive tract are also described, all microscopically true adenomata. In these as in the uterus polypoid excrescences are a common characteristic. Single benign polypi are, of course, not uncommon both in uterus and intestine; in the latter also there may occur extensive multiple polyposis without malignant characters, but this condition in either situation should always suggest malignant adenoma. The author considers that this type of growth is distinct from true carcinoma, in that it retains its glandular characters both in primary growth and metastases, that the cells are of one constant type, and that no solid masses or multiplied layers of cells are formed.

(313) Hæmorrhage in a Case of Placenta Velamentosa.

Kaygrier (*Sem. Méd.*, November 21st, 1900) mentions a variety of puerperal hæmorrhage, which, as distinct from placenta prævia and accidental hæmorrhage, is dangerous to the child only and not to the mother. He relates a case in which pregnancy was normal and no bleeding took place until the rupture of the membranes. When the patient was first seen the fœtal heart sounds could not be heard; otherwise nothing abnormal was discovered. A stillborn child was delivered naturally. Examination of the after-birth showed that the cord was inserted 5 cm. from the edge of the placenta, and at the point where rupture of the membranes had occurred a torn umbilical artery was seen. A careful search for pulsation over the presenting membranes is therefore advisable as a routine measure. If such pulsation is discovered the proper treatment is early artificial rupture of the membranes as far away from the pulsating area as is practicable.

(314) Dermoid Tumour of Pelvic Connective Tissue.

Beyea (*Amer. Journ. Obstet.*, April, 1900) adds to literature a case of this rare disease, with a good summary of earlier reports. Sänger in 1890 first showed that a tumour may develop primarily in the subperitoneal connective tissue independently of the ovary. De Quervain proved this theory by the report of a case occurring in a man. Beyea's patient was a coloured woman, aged 38. Both uterine appendages had been removed when she was 26. Since that operation the period had never been seen again. Six weeks before she came under Beyea's observation she began to suffer from backache and tenderness in the right iliac fossa. There was also a hernia of the old operation wound. A tender cystic tumour projected above the right groin, half way to the umbilicus, and extended downwards into the right fornix, displacing the small atrophied uterus to the left. Beyea operated and found that the tumour completely separated the layers of the right broad ligament. It was enucleated, the bleeding from the cavity was not uncontrollable, but with the uterus unavoidably wounded it was otherwise, so that organ was removed. Convalescence was uncomplicated. The tumour was a bilocular cyst, was 4 inches in diameter. Its loculi contained yellow liquid grease, which solidified on cooling, its inner wall bore skin, rudimentary mammary and sebaceous glandular tissue, bone, cartilage, a little hair and much fat. There were no indications of remaining ovarian tissue; the surfaces of both ligaments close to the uterine cornua were smooth and normal.

(315) Calcified Ovarian Fibroma: Extreme Chronicity.

Pokrovsky (*Khirurghi*, January, 1900) notes a singular case where a very little tumour had existed for some twenty years, according to the patient's own report. For two years it caused occasional paroxysmal pain, especially when it slipped into the abdomen out of the pelvic cavity. It could be clearly defined by placing the patient in the genu-pectoral position, then it slipped over the pubes, and felt stony. It was freely movable and well pedunculated. As it worried the patient, who was 58, it was removed by abdominal section. The tumour measured 2 inches by 2½ inches, but weighed 8 ounces, and was of stony hardness. It proved, on microscopic examination, to be a fibroma completely calcified. Traces of ovarian tissue were detected. There was no ascitic fluid in the peritoneal cavity.

THERAPEUTICS.

(316) Protection against Malaria.

Experiments under the direction of Professor Grassi (*Centralbl. f. Bakt.*, November 5th, 1900) have been carried out at Paestum with a twofold object: (1) To prove conclusively that malaria can be transmitted only by the bites of *Anopheles*; (2) to overcome the difficulties of the practical application of this discovery, and to decide on the means to be taken to rid Italy of malaria. Paestum was chosen on account of the special prevalence of the disease there. Here during the malaria season most of the inhabitants either leave or spend their night on the surrounding hills; a certain number, for example, the railway officials, have to remain, and it was determined to use these for the attempt at protection. In the first place all those who showed any trace of malaria during the healthy season (January to June) were treated with quinine; and secondly, all under observation were protected from the bites of mosquitos by nets during the infective period. The first infected mosquito was found on June 14th, and, allowing twelve days' incubation, malaria was anticipated on the 26th; as a matter of fact, the first case occurred on that date outside the zone of experiments. Three cases of relapse occurred during the infective season in persons who had falsely asserted that they had not previously had the disease. The preventive rules laid down were: to keep within the protected dwellings from sunset to sunrise, and in the case of officials who had duties during this time to wear light veils and thick cotton gloves. The houses were protected everywhere, even the chimneys, with wire netting. Here and there an *Anopheles* was found in the houses, but they were for the most part caught before they had stung anyone. All the persons under observation were visited twice a day; precautions were taken against their procuring any quinine, and yet all continued free from malaria. The number was 104. In the country surrounding the protected zone, on the other hand, the disease was general, and affected by far the majority of the inhabitants, even when living on farms in high situations. The twofold object of the experiments was therefore attained, and the practical protection from the bites of *Anopheles* shown to be feasible.

(317) Treatment of Alopecia.

Scheffer (*Méd. Mod.*, May 19th, 1900), after pointing out that the generally assigned causes of this disease are microbic and nervous, describes a mode of treatment which attempts to control the former by sublimate and the latter by pilocarpin injections. Pilocarpin is chosen from its property of sweat inducing. The sweat glands are analogous with the hair follicles, both embryologically and structurally, hence the suggestion that pilocarpin may equally stimulate the nervous centres of hair production. It is well known that in many diseases in which the skin takes up extended excretory functions there is an increased production of soft new hair in certain regions. Additionally, pilocarpin produces a local vaso-dilatation. The alopecial patch is well cleansed with 90 per cent. alcohol, and a syringe is then filled with the two medicaments: it holds about 12 minims. The upper third is filled with $HgCl_2$ solution 1 in 1,000, the second with 1 in 200 pilocarpin nitrate, and the lower third with 1 in 1,000 $HgCl_2$. The needle is introduced parallel with the scalp, and just underneath the epidermis; it is then emptied, and leaves a small lentil-sized swelling. Such is repeated around the periphery of the patch, and in a circle within it, the punctures being about 1 cm. apart. An alopecial patch the size of a 5-franc piece requires about 12 punctures. The *séance* should be repeated every other day for some six or seven days. The immediate effects produced are an anæmic zone followed by a marked vascularity lasting for several hours. Five or ten minutes after the injection drops of sweat appear on the vascular zone, and this exudation continues for an hour. The secondary results (tabulated from some 60 cases extending over three years) are immediate arrest of the alopecia extension, and a gradual regrowth of hair first light and then darker—from periphery to centre. This growth

should be evident after four *séances*. but in all cases the treatment should be persistent. Its extent is indicated by the size of the bare patch, the age of the lesion, the position—temporal and occipital alopecia is always the more difficult to obtain good results—and the age of the subject. The treatment has yielded most successful results.

(318) Iodine Parotitis.

GRÖN, (*Norsk. Mag. f. Laegevidensk*, lxi, 685, July, 1900) describes the case of a man, aged 26, under treatment for repeated returns of syphilitic manifestations. He developed an acute attack of parotitis upon many of the occasions on which he took iodide of potassium. Upon sixteen separate occasions he was treated with the iodide, and on eight of these parotitis followed, sometimes as the result of small doses, at other times not until large quantities had been given. On yet other occasions he took large doses without any affection of the parotid. The continued use of the iodide did not make the parotitis worse; in fact, the recovery was always complete. The only medicine which seemed to hinder the toxic action of the iodide was the bromide of potassium if given simultaneously. Only on one occasion was there any other manifestation of iodism (headache, with nasal, pharyngeal, and conjunctival catarrh). There was no albuminuria. Grön believes that the cause of the parotitis was idiosyncrasy.

(319) Aluminium Salts as Disinfectants.

AUFRECHT (*Deutsche aertzl. Zeitung*, February, 1900) caused experiments to be made in his laboratory in order to determine the comparative value as antiseptics of acetate of aluminium in the form of the 8 per cent. liquor aluminii acetici of the German *Pharmacopœia* ("liquor Burowii"), and of the aluminium acetico tartaricum (acetotartrate of aluminium), which has been recently introduced by Athenstaedt under the name of "alsol." Alsol in a 5 per cent. solution destroyed the spores of anthrax in ten hours, acetate of aluminium in an 8 per cent. solution in two hours, while carbolic acid in a 5 per cent. solution had no effect whatever on their development. In the case of streptococcus pyogenes, staphylococcus pyogenes aureus, the gonococcus, and the tubercle bacillus, however, carbolic acid has a greater bactericidal power than acetate of aluminium. The combination of the acetate with the tartrate greatly raises the bactericidal power, so that alsol is considerably more potent than carbolic acid.

PATHOLOGY.

(320) The Cause of Diabetic Coma.

GRUBE (*Arch. f exper. Pathol.*, Bd. xliv, s. 349) has conducted a series of experiments to test the opinin of Sternberg that β-amidobutyric acid is the active agent in the causation of diabetic coma. He has injected this substance into cats, and records the general, respiratory, and circulatory disturbances resulting. In all cases he was able to produce, by large doses, a coma-like state, while control experiments with other substances were negative. Respiration was conspicuously influenced, and the type was similar to that observed in diabetic coma. The force of the heart beat was increased by the administrations, but the blood pressure was not affected. Acetone was frequently present in the urine. The author concludes that the condition produced in cats by large doses of this substance is very similar to diabetic coma in all its symptoms.

(321) Blastomycetes and New Growths.

PETERSEN AND EXNER (*Beitr. z. klin. Chir.*, Bd. xxv, 1899) have made a series of culture experiments on this subject. As a result, they express their agreement with the opinions of Busse and others that up to the present there has been no satisfactory proof of any causal relationship between yeast forms and malignant tumours. (1) The cell inclusions in carcinomata, which have been looked upon as parasites, have but very slight resemblance to blastomycetes. (2) A pure culture of yeast from a true malignant tumour has hitherto been so seldom obtained that probably it occurs only as a contamination or as a saprophyte. In 22 cases of aseptic carcinomata and sarcoma the authors have not been able to cultivate such an organism, though they have used many different media and methods. (3) The diseases which have been shown to be due to this class of organism have no resemblance to malignant tumours worth the name. (4) Although pathological tumours have been produced by the experimental inoculation of blastomycetes, they belong to the granuloma class rather than to that of true new growths. At the most it has been shown that certain malignant lymphomata can be produced by such infection.

(322) The Pathology of the Blood.

FOA AND DEMEL (*Arch. Ital. de Biol.*, July, 1900, two papers) record the results of their preliminary investigations of normal and pathological blood stained with Ehrlich's neutral red. They claim that these throw much new light on the origin of the red corpuscles. They state that the coexistence of nucleus and granules in the erythroblasts is easily demonstrated, that the former is actually expelled in the formation of red corpuscles, but that in all probability the expulsion is preceded by an escape of many of its granules into the protoplasm, where they may be fixed by neutral red. The authors have discovered that in normal blood red corpuscles containing such granules are present to the extent of about 0·5 to 0·8 per cent. of the total number. After repeated bleeding this proportion may rise as high as 18 per cent., and as in the organs in which red corpuscles are formed the proportion is also very high, it is deduced that these granular red corpuscles are young forms which have entered the circulation soon after losing their nuclei. Their presence is hence an index of the degree of functional activity of the hæmopoietic organs and of the state of the circulation in the marrow. Further experiments showed that in most cases of artificial anæmia, whether brought on by bleeding or by the administration of pyridine, the diminution in the number of red corpuscles was associated with an increase in the proportion of those with granules, which did not, however, come on till the recuperative period. In a case in which the granular forms did not reappear the animal rapidly succumbed. Quinine caused a great diminution in their number followed by an increase after two or three days. The injection of lecithin also produced a remarkable diminution, so that there were no granular red corpuscles in the blood or marrow and very few erythroblasts; the blood condition did not return to normal for about 10 days. Hence it seems that certain influences tend to favour the maturation of existing red corpuscles rather than the formation of new ones. The authors suggest that this maturation occurs normally in the marrow and that the corpuscles escape into the blood after being deprived of their granules; in circumstances of great need and circulatory disorder young granular corpuscles enter the circulation just as do the normoblasts. It has further appeared that infection of an animal, whether immunised or not, causes a rapid diminution in the granular red corpuscles, while the hæmoglobin and number of corpuscles alike remain constant. Finally, in a young anæmic girl the granular erythrocytes were almost absent, but after 14 days of treatment with iron had attained a proportion of 6 per cent. of the total red corpuscles.

(323) The Pancreas in Relation to Sugar Reduction and Diabetes.

UMBER (*Zeits. f. klin. Med*, Bd. xxxix, p. 13) has carried out a series of experiments to test the observations of Blumenthal that the expressed tissue juices of the liver, spleen, and pancreas have a reducing action on grape sugar, most active in the case of the pancreas, least in that of the spleen. Umber finds that if the pancreas is excised with aseptic precautions and all foreign matter excluded, the expressed juice has no reducing capabilities. He also excised portions of pancreas from a living dog and added them to a sugar solution, but four days' digestion produced no result. Experiments were also made on the glycolytic action of blood; this was taken from different vessels, including the pancreatic vein, directly into sterile slightly alkaline sugar solution; a distinct though small reduction was observed, but there was no difference between the blood from the pancreatic vein and other specimens. These experiments would seem to disprove the idea that the derangement of glycolysis in diabetes is due to the absence of certain pancreatic sugar-reducing ferments.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(324) Thoracic Aneurysm Presenting Intermittently through the Sternum.

Cabot (*Amer. Journ. Med. Sci.*, April, 1900) reports the following case: A married woman, aged 42, had a tumour the size of a lemon and the shape of a stump of a cow's horn over the manubrium sterni; its apex was black and gangrenous, and was surrounded by a deep red areola. The tumour was soft and elastic, and showed expansile pulsation synchronous with the heart beats. There was a soft blowing murmur over it. Below this tumour, and on a level with the third and fourth costal cartilages in the middle line, was a second pulsating mass, larger, flatter, and less inflamed than the other. It was not elevated more than half an inch above the surface, and though it rose and fell with each heart beat, the pulsation was not expansile. The heart sounds were transmitted through the tumour, but there was no murmur heard over it. The heart's apex was in the fifth interspace in the nipple line. The radial pulses were equal and synchronous, there was no "tracheal tugging," the pupils were equal and reacted normally. The history given was that the upper swelling had appeared seven years previously, and had quickly attained its present size. Under potassium iodide internally it disappeared completely. Since then the tumour had come and gone several times, becoming more noticeable during periods of hard work, and disappearing usually while the patient was taking iodide of potassium. The general health had been good, and there were no pressure symptoms. There was nothing suggestive of syphilis except the facts that there had been seven successive miscarriages, and that there were scars on the back, chest, and arms, which were attributed by the patient to chickenpox and boils. The tumours were diagnosed as gummata of the sternum by Cutler, and 90 grams of potassium iodide were given daily. Three days later the upper tumour burst, and gave exit to a quantity of bloody puriform material, but no blood. A week after this the lower swelling was incised, and material similar to that from the upper tumour was evacuated. Three weeks later there was no prominence at the site of either tumour. There was, however, a sinus 1 inch below the sternal notch in the middle line, which passed at first directly backwards, and then downwards, parallel to, and presumably behind the sternum for 3 inches. The patient remained in good health for about two months, and then suddenly fell dead, with blood gushing from the chest. There was no necropsy. During life radiographs were taken, and though they showed clearly a tumour in the region of the aortic arch, the significance of this was not understood. No gap was present in the sternal shadow, and the false inference was drawn that no perforation was present, although the position of the vertebral column would prevent even a large perforation from showing. The diagnosis of aneurysm, in view of the fatal termination, was almost certainly correct. The probe showed that the hole in the sternum was small. Probably then at one time blood would ooze through and clot outside the sternum, while at another the clot inside the aneurysmal sac would become sufficiently firm to prevent blood from escaping through the sternum. What was the exact nature of the cheesy material evacuated, and whether it was broken-down clot is uncertain. It is remarkable that an aneurysm could erode and perforate the sternum in two places without any pain or symptoms of pressure, and it is possible that the process in the sternum was partly gummatous.

(325) Hydatid Cysts of the Liver.

Chauffard considers some of the points which are of assistance in the diagnosis of this condition (*Journ. de Méd.*, March 10th, 1900). A good deal depends on the stage of the disease. Thus, in the first or aseptic stage corresponding to the active life of the parasite there is practically nothing to go upon. The second stage, or septic necrosis, with death of the parasite; and the third is the stage of septic necrosis in which there is infection of the neighbourhood of the cyst. A case quoted by the author is interesting as throwing some light on the earlier symptoms. The patient was a woman, aged 30, who for four years had suffered from vague pains in the region of the liver, some dyspepsia with a remarkable inability to take any fat or oil, with several attacks of urticaria and frequent sharp pains in the right shoulder. There was no jaundice, no ascites, and no enlargement of the spleen. After a considerable time it was possible to ascertain some increase in size of the hypochondrium, and about the same time epistaxis occurred at intervals. A curious symptom remarked in this case was the intermittent elimination of methylene blue in the urine. This phenomenon, the writer observes, is met with in other affections of the liver, and seems to indicate a considerable degree of involvement of that organ. In this instance, taken in conjunction with the occurrence of urticaria, it suggested the diagnosis of hydatid cyst of the liver, notwithstanding that there was no irregular prominence to be found on palpation, but a general increase of liver dulness observed. The diagnosis was verified by an exploratory puncture. Chauffard, however, strongly deprecates this procedure, as he once met with a case in which a few moments after puncture the patient was seized with an intense pruritus but without any urticaria. Shortly afterwards purpuriform attacks came on, and death occurred within twenty-five minutes. Nor is this the only case on record, for it would seem, according to the lecturer, that when a small amount of hydatid fluid is withdrawn some toxic material is rapidly absorbed from the remainder. The safest procedure, therefore, is when puncturing to be prepared to evacuate the cyst completely. Under these circumstances there does not seem to be the same danger of toxic absorption. In conclusion, it is pointed out that while in many cases a local projection from the liver together with negative evidence of other conditions will indicate the presence of hydatid, there may be cases without any such physical signs, but in which a diagnosis may still be made by careful attention to the symptoms as demonstrated by the writer, notably the occurrence of urticaria and the methylene blue phenomenon. The sign called "hydatid fremitus" Chauffard considers hardly worth mention.

(326) Glycosuria in Tramps.

G. Hoppe-Seyler (*Münch. med. Woch.*, April 17th, 1900) has observed several cases of transitory glycosuria in persons, especially tramps, who for a long time have led an irregular life, while exposed to all weathers and frequently in want of sufficient, or at least properly-prepared and digestible, food. The course of the glycosuria and the conditions were always similar. Glycosuria was found on admission to hospital, but quickly disappeared with an abundant mixed diet, which included a large proportion of carbohydrates, and did not return even when 100 to 200 grams of grape sugar were given on an empty stomach. This form of glycosuria can depend neither on disturbances in the medulla oblongata nor on latent diabetes, and is probably caused by a disordered function of the digestive organs, especially the liver and pancreas—that is, in general terms, by malnutrition and its consequences. The liver was enlarged in all the cases, but there were no other signs of cirrhosis.

(327) Myositis Ossificans.

Lydia M. De Witt (*Amer. Journ. Med. Sci.*, cxx, 295, September, 1900) gives details of two cases of myositis ossificans affecting the muscles of the leg, in both of which there was thrombosis of the femoral vein, and in both of which the process was not discovered till the necropsy. Warthin performed the *post-mortem* examinations. In one instance the cause of death was widespread tuberculosis. The authoress believes that the primary condition is an inflammatory process in the intermuscular connective tissue, resulting in degeneration of the muscle fibres; the second condition seems to be the establishment of the processes of repair and the formation of a tissue rich in fibroblasts and small blood vessels; but before this process can be completed and mature connective tissue formed it is interrupted by the change of a part of the tissue into trabeculæ of firm osteoid substance, which becomes calcified, while the parts enclosed by the trabeculæ change to bone marrow. With

regard to causation the authoress notes that the alleged exciting causes are often too slight to be active, while the evidence in favour of atavism, direct heredity, and embryonic disturbance is but small.

SURGERY.

(328) Inflammatory Pyloric Tumour: Disappearance after Gastro-enterostomy.

DEMOULIN AND TUFFIER (*Bull. et Mém. de la Soc. de Chir. de Paris*, October 31st, 1899) publish the case of a naval lieutenant, aged 32, who suffered from severe dyspeptic symptoms early in 1897, aggravated by a diet of preserved meat during a cruise round the coast of Ireland. Early in 1898 a hard swelling developed in the epigastrium. Medical treatment at Vichy and elsewhere was of no avail. His weight fell to 77 lbs, the cachexia was marked, and emaciation extreme. The swelling was as big as an orange, movable transversely, and following respiratory movements; it was tough rather than hard. Directly the patient swallowed anything, even a few spoonsful of water, great distension of the epigastrium with severe pain occurred, due evidently to contraction of the stomach for forcing its contents through the pylorus. Malignant tumour was diagnosed, and Demoulin operated on December 1st, 1899. An incision 4 inches long was made in the middle line above the umbilicus. A soft tumour of the size of an orange lay around the pylorus and adjacent parts of the stomach and duodenum. It felt like a fatty growth, and was not adherent to any surrounding structures; a stellate cicatrix on its upper aspect shows signs of a healing ulcer. There were no enlarged glands in the neighbouring peritoneal folds; the liver and gall bladder were healthy. The patient was in so exhausted a condition that a pylorectomy was considered impracticable. Demoulin therefore performed a Van Hacker's gastro-enterostomy (posterior and transmesocolic), leaving the tumour alone. A litre of salt solution was injected under the skin directly after the operation. The patient's life was in great peril for several days from ether-bronchitis. On the third day hæmatemesis occurred, and nearly a pint of blood was vomited. By the tenth, the patient was able to eat fish and fowl without any bad effects. On the twentieth, Demoulin for the first time palpated the epigastrium; to his surprise the tumour could no longer be felt, its site being marked by a little thickening which vanished within ten days. In May the patient was again on active naval service; no local symptoms remained, but he was troubled with an obstinate cough and free expectoration.

(329) Insanity after Extirpation of Brain Tumour.

BAYERTHAL (*Münch. med. Woch.*, 1899, No. 46) publishes a case recently read at the Munich Congress of Naturalists and Physicians which is particularly interesting, as the patient after the extirpation of a tumour of the brain recovered completely from acute hallucinatory paranoia which had supervened during the development of the tumour. A merchant of 29, married three years, without family, without hereditary taint, though at the age of 18 he began to suffer from strumous suppuration of the cervical glands, was attacked in January, 1897, with symptoms of motor and sensory irritation of the cortex (Jackson's epilepsy), succeeded in the course of 21 months by paralysis of the left leg and arm, to which (since September 1898) was added, probably by reason of visual hallucinations, a mania of persecutions; consciousness was hardly obscured at all. From its progressive character the disease was referred to a tumour in the paracentral lobe, perhaps involving the arm centre. This view was supported by a circumscribed tenderness to percussion over the right parietal corresponding to the position of the supposed tumour. An operation, commenced under choroform and morphine narcosis had to be interupted on account of the condition of the patient's pulse, but Professor Heidenhain was able to complete it (without chloroform) two days later and removed a subcortical solitary tubercle about the size of a small walnut from the paracentral convolution. The under side of the tumour must have been close to the corpus callosum. The mental condition of the patient may be said to have improved from the time of the operation; the paralytic symptoms also improved steadily, the convulsions in the left arm disappeared very gradually and slowly, the patient was discharged on the sixty-fifth day after operation walking well with a stick. At the present time (nearly a year after the operation) he is quite well mentally, drags his foot still, but can walk for 45 minutes without fatigue. He has dragging pains and transitory stiffness in the left limbs. He has had repeated attacks of convulsions (4), extending from the left leg to the arm, face and tongue muscles of the same side and followed by loss of consciousness.

(330) The Regeneration of the Crystalline Lens.

RANDOLPH (*Johns Hopkins Hospital Reports*, vol. ix), as the result of his experiments, draws the following conclusions: (1) Regeneration of the lens in the rabbit's eye occurs only when some portions of the lens are left behind at the extraction. (2) Removal of the lens in its capsule is followed by a negative result. (3) Panophthalmitis will lead to a negative result. (4) The volume of the regenerated lens may be equal to that of the original lens. (5) The regenerated mass is lenticular, though sometimes it is ring-shaped and at other times semilunar. (6) The reason why positive results occur so much less frequently than negative ones is because we are unable to protect the animal from infection after the operation. We have nothing to take the place of the after-treatment which is always employed in cataract operations upon human beings. (7) Theoretically one would suppose that the longer the animal were allowed to live the greater would be the volume of the regenerated mass. This, however, was not the case. In one instance, when an animal was killed fifteen months after the extraction of the lens, the regenerated lens was about equal in size to that seen in a rabbit killed after six weeks. (8) A mild iritis, lasting for a week or ten days after the operation, is conducive to a successful result. This may be explained by the increased vascularity of the parts which lie next to the lens. (9) In the case of the newt, extraction of the lens is followed by its regeneration. (10) Regeneration (in the newt) occurs even when the lens has been removed in its capsule, so that the new lens must take its origin from tissue having a different physiological value, and, as the experiments of Wolff have shown, this structure is the iris. He is not sure that the phenomena noticed in these experiments on rabbits and newts find any conspicuous analogy in the history of cataract in human beings, although activity of the capsular epithelium after the extraction of cataract is often to be seen.

(331) Resection in Tuberculous Disease of of the Hip.

KIRMISSON (*Rev. d'Orthop.*, No. 3, 1900) in reviewing a recent discussion at the Société de Chirurgie de Paris on the surgical treatment of hip-joint disease, states that he has been led to take a very unfavourable estimate of the utility of resection for such disease in young subjects. This operation, he states, is undoubtedly a serious one, is often followed by return of the disease, and its results from an orthopædic point of view are inferior to those of a strictly conservative treatment. Strong objection is raised against the frequent practice of making free incisions into cold abscesses associated with hip-joint disease and spinal caries. As soon as such an abscess is accessible the author treats it by simple puncture, and the injection of iodoform and ether. By such treatment practised under strict aseptic precautions septic mischief, which so often occurs after free incision, may be avoided. Much stress is laid on the importance of rest in bed during the whole of the acute stage of hip-joint disease. This view, it is stated, is confirmed by the fact that there is now a general tendency in the surgical practice of the United States and other countries to discontinue the ambulatory method of treating coxalgia. This method, it is held, is likely to provoke corrosion of the articular surfaces, and thus to result in suppuration and deformity of the joint. The patient, Kirmisson asserts, should be kept at rest until the affected limb is quite free from pain.

MIDWIFERY AND DISEASES OF WOMEN.

(332) Placenta Prævia.

AMADEI AND FERRI (*Il Policlin.*, November 17th, 1900) reported to the Italian Gynæcological Congress a series of 97 cases of placenta prævia in 5,136 cases at the Milan Maternity hospital, a propor-

tion of 1.89 per cent. Eleven were in primiparæ and 86 in multiparæ, and in only 24 cases did the mother reach the full term, all but 1 of these 24 being marginal. In 5 cases the mother died: (1) Severe anæmia due to hæmorrhage from the placental site and from a laceration of the cervix; (2) embolism on the second day; (3) embolism during intra-uterine irrigation after delivery; (4) severe anæmia during podalic extraction; (5) acute pleuro-pneumonia on seventeenth day, after dilatation of cervix and use of forceps. The treatment was varied; in 2 cases it was medical only. Plugging was used in 10 cases, loss of 1 mother and 1 child; rupture of amnion in 16 cases of longitudinal position of the fœtus, no mother and 5 children lost; in 2 cases of rupture of the sac after external version 1 child was lost. In many cases the rupture of the amnion failed to stop the hæmorrhage. Podalic extraction was practised in cases of marginal placenta prævia, where the cervix was more or less dilated, enough to permit the bringing down of the limb. In a case of central placenta prævia Tarnier's method was used. (In this hospital continuous traction by means of a weight is often adopted to secure slow extraction with great advantage to the mother.) Turning was done 42 times; 23 by the clasical method and 19 by Braxton Hicks's method, with 8 and 7 fœtal deaths respectively. Forceps were used in 7 marginal cases; in 1 case the mother died (pleuro-pneumonia). There were 3 craniotomies in cases of dead fœtuses with excellent results as regards the mother.

(333) The Psychoses of the Menopause.

CHAPIN (*Philad. Med. Journ.*, August 25th, 1900) endeavours to show that the danger of insanity beginning during the menopause has been exaggerated. Out of 8 320 women admitted into various institutions, only 188 were specified as becoming insane at the menopause, nor was it clear how many out of the 188 went mad through the special changes in the genital tract at that period of life. The statistics of the Pennsylvania Hospital show that between the ages of 45 and 55, representing the usual range of the menopause 975 men and only 876 women were admitted into that institution. S Weir Mitchell, in his Analysis of 3,000 Cases of Melancholia, shows that the exact percentage of cases between the ages of 45 and 50 was 20.2 in men and 21.4 in women, the difference being very, very slight, and once more not due, on any distinct evidence, to the local changes of the menopause. The dread or risk of insanity at the approach of the menopause in a woman ordinarily of sound mental and psychical health and inheritance has no better foundation than a popular delusion based on borrowed fears.

(334) Ossifying Enchondroma of Ovary.

BART (*La Union Medica*, No. 4, 1900) relates a remarkable case, where an extremely tough and deeply lobulated tumour filled the abdomen of a woman, aged 38, extending for 2 inches above the umbilicus. It had grown slowly. The patient suffered badly from pressure symptoms, the uterus was pushed far down in the pelvis, and the bladder much displaced. The operation was simple, and recovery rapid. The tumour weighed 14½ lbs. It had a stroma of fibre with cartilage between the meshes; the cartilage was ossifying at certain points.

THERAPEUTICS.

(335) Treatment of Tetanus with Subcutaneous Injections of Brain Emulsion.

KROKIEWICZ of Cracow (*Wien. klin. Woch.*, August 9th, 1900) publishes two cases of traumatic tetanus treated by hypodermic injections of brain emulsion. (1) A medical man, aged 33, cut his right index finger while making a necropsy on an exhumed body; twenty hours later tetanic symptoms appeared in the right arm. On the eleventh day general tetanic spasms set in and death seemed imminent. There were profuse sweating, cyanosis, pyrexia (100.5° F.), rapid respiration (32), and a thready scarcely perceptible pulse. With the aid of large doses of champagne he was moved safely a five hours' railway journey to the Cracow hospital, where he was treated with morphine hypodermically, iodide and bromide of potassium by the mouth, and inhalations of ether. Nevertheless a very severe tetanic spasm occurred and lasted three and a half hours. An hour and a half after this had abated an unfiltered emulsion of the entire brain of a rabbit was injected hypodermically, and this procedure was repeated on the second and fourth succeeding days. After the first injection there was no repetition of the tonic convulsions, the temperature fell gradually, the respirations became 16 to 18 in the minute. An occasional sensation of stiffness and twitching in isolated groups of muscles, however, persisted for three weeks. The third injection produced an aseptic abscess, which healed rapidly after incision. Chloral hydrate, sulphonal, iodide and bromide of potassium, strophanthus, caffeine, digitalis, and valerian were also prescribed for various symptoms as they arose. After a tedious convalescence recovery was complete. (2) A woman, aged 35, ran a splinter into the right thumb. Six days later trismus appeared, with dysphagia, and laboured breathing and phonation. Shortly afterwards the spasms involved the muscles of the whole body. On the tenth day of the disease, after the usual methods of treatment had failed, an emulsion of one rabbit's brain was injected under the skin of the thorax. The next day the convulsions were frequent, but less severe, so that swallowing was possible for the first time, and the speech became distinct. On the twelfth day there was a further improvement: after a prolonged and uninterrupted sleep there was no spasm between 10 A.M. and 3 P.M. The patient was then visited by some Jewish relations, who compelled her—"from religious motives"—to get up and walk about for about thirty minutes, although the tetanic spasms reappeared. Early next morning death occurred suddenly. Both these were severe cases of tetanus, and both had failed to improve under pharmaceutical preparations. The rapid improvement in the first case was remarkable, and recovery would have probably taken place in the second but for the fanatical relations. This method of treatment was first practised by the writer in 1898, after Wassermann and Takaki had experimented on animals. Since then 10 cases had been reported, with 8 recoveries. In both the fatal cases there was a temporary improvement, and in one there were necessarily fatal lesions, including an impacted calculus in the ureter and a ruptured uterus. In all drugs had failed, and in one (Schuster's) the brain emulsion succeeded after two injections of antitetanus serum into the subarachnoid space (Jacob's method) had failed. These results compare very favourably with those obtained by antitetanus serum, with which the mortality is, according to Holsti, 43 per cent.

(336) Treatment of Psoriasis by Oil of Cade Baths.

BALZER AND MONSSEAUX (*Journ. des Praticiens*, No. 21, May, 1900, p. 321) recommend for the treatment of psoriasis oil of cade in the form of baths. The oil of cade is added to a soft soap emulsion. The following are the formulæ: Soft soap, 100 grams; water, 200 grams. To this emulsion the oil of cade is added in the proportion of: Oil of cade, 100 grams; soap emulsion to 250 c.cm. The latter represents the amount to be used for one bath—30 gallons. As to the bath, it must be prepared as follows: First put the oil of cade emulsion in the bath; then let the water run in; or the emulsion may be well stirred up in a bucket of hot water beforehand. The patient must before the bath use plain soap and water to get off the scales. The authors do not state the temperature of the bath or the time the patient is to remain in it. They had good results as far as the individual attacks were concerned; but of course this treatment does not cure the complaint. In some of their cases oil of cade was also rubbed in and applied on lint locally in addition to the baths.

(337) The Treatment of Venereal Sores with Itrol.

WERLER (Reprint from *Lassar's Dermatolog. Zeitschr.*) has obtained good results in 40 cases of venereal chancres by the use of itrol (silver citrate). The preparations employed were a 1 in 4,000 solution in water, and a dusting powder of the pure silver citrate, both of which should be put up in yellow glass bottles. The solution can be applied on compresses, and is much less irritating to the skin than mercury or carbolic acid lotions. It is still better to apply it daily by means of a spray. After the sore is thoroughly cleansed with the lotion, it is dried, covered with a thin layer of the powdered itrol, and en-

veloped in cotton wool. If the chancre is very painful, a 5 per cent. solution of cocaine may be applied before the first dressing. Itrol is an energetic bactericide, which acts continuously, and penetrates deeply among the diseased tissues. It therefore produces a rapid cessation of destructive ulceration, and converts the infected chancrous surface into a healthy granulating wound. It does not cauterise or destroy healthy tissue, and therefore causes no retention of discharge behind a slough. The writer never met with secondary buboes among his cases, and the treatment has the great advantages of being completely odourless, practically painless, unirritating, and cheap. It is suitable for simple soft chancres, for gangrenous and phagedænic sores, and for the rarer diphtheroid ulcers. Unless the case were very urgent, the writer would always attempt to arrest phagedæna with itrol, before resorting to the actual cautery. Even hard sores heal rapidly with itrol, and in cases in which the diagnosis between simple and primary syphilitic sores is doubtful it is always indicated.

PATHOLOGY.

(338) The Tubercle Bacillus in "Scrofulous" Glands.

D'Arrigo (*Centralbl. f. Bakt.*, Bd. xxviii, No. 16) has previously described a method of staining the tubercle bacillus which demonstrates it clearly and with certainty in tissues and organs. He has used this method to investigate the questions: (1) Whether the bacillus is present in so-called scrofulous glands; (2) what phases the bacillus passes through in these glands; (3) what histological alterations it produces. He has arrived at the following conclusions: All so-called scrofulous glands are truly tuberculous and contain the bacillus. Between the ages of 4 and 12 this form of tuberculosis is especially common in the cervical and submaxillary glands; between 12 and 30 the axillary glands in women and the inguinal in men are chiefly affected. The bacillus is found to present a considerable range of polymorphic forms—rods short and long, thick and slender, single and connected in chains, and in addition certain round or oval involution forms. The usual forms of the bacillus are found in the small glands in the early stages of the condition; the long forms and chain forms in old caseous foci; the oval and round forms in glands containing young tubercles either free or in the lymphocytes. The greater number of organisms are present in the peripheral parts of the gland, few in the centre and near the hilus. They are in the perivascular lymph spaces in the early stages, and are more numerous in these early stages than later. The histological changes at first consist of hyperæmia, lymphoid infiltration, and the formation of necrotic coagulation areas; later the leucocytes are transformed into large epithelioid cells, and extensive fatty degeneration occurs. True giant cells are uncommon. The lymphocytes exhibit considerable phagocytic properties. The lymph glands constitute a strong barrier against the entrance of the bacillus. They act as filters, and can lessen the virulence of the organism. When, however, the intrusion of the bacillus is considerable and long-continued, and when the resistance is enfeebled, the bacilli may find their way out of the glands into distant organs, and may also serve as foci from which bacilli find their way into the blood and cause miliary tuberculosis.

(339) A New Pathogenic Fungus, formerly Described as a Protozoon.

Ophüls and Moffitt (*Philad. Med. Journ.*, June 30th, 1900) records the following case of a man, aged 19, who entered into hospital suffering from pleural effusion. One gallon of fluid was drawn off by tapping. There was irregular fever, at times reaching 104° to 104 4°. The diazo-reaction was present, but not the Widal. The joints of the elbows, wrists, shoulders, knees, and ankles were also affected, and a painful, fluctuating swelling developed over the left eye. In the left supraclavicular fossa a large gland was noticed later. He had cough, with muco-purulent (occasionally blood-stained) sputa, but no tubercle bacilli were found. The diagnosis was septicæmia. The patient died after being a fortnight in hospital, and the necropsy revealed the following conditions: Nodular masses, with necrotic centres in the right lung, the tissues between the nodules being atelectatic; several abscesses in the middle lobe of the lung; nodules like tubercles in the right lung, and a large abscess in the mediastinum. The pillars of the diaphragm were infiltrated with pus, and there were necroses and abscesses in the retroperitoneal lymphatic glands. An encapsulated empyema was found in the left side. The spleen was soft and pulpy, with yellow patches of softened tissue in places. The kidneys showed cloudy swelling, with miliary nodules undergoing central caseation and miliary abscesses with thick membranous walls, mostly in the pyramids. The liver showed cloudy swelling and fatty infiltration, but no visible nodules. There was purulent ostitis and periostitis in the frontal bone and left tibia, and abscesses in the lymphatic glands above described as enlarged and affected. Sections of the liver showed very many microscopic nodules with necrotic centres. Microscopic examination of the pus, lungs, spleen, liver, and kidney showed parasitic organisms, which in the last three organs were found in pure culture. In the abscess over the eye these were met with in combination with staphylococci and streptococci, and in the left pleural empyema pseudo diphtheria bacilli were also found. The parasitic fungi were spherical, encapsuled, highly refractile, with granular protoplasm, and staining well with aniline dyes and hæmatoxylin. They grew up to a size of 30 inches in diameter, and were perfectly spherical. They were not motile, and in the larger sizes vacuoles could be seen. After reaching the adult stage the encapsuled protoplasm breaks up into about a hundred or more spore-like bodies, also non-motile, and which grow into adult forms without transformation. Cultures made on agar resulted in the formation of a mould developing a mycelium. The colour was white with a faint tinge of yellow. Injections of cultures into guinea-pigs produced local chronic suppuration, and secondary nodules and abscesses showing the organism in pure culture. Growth in a free medium without obstruction gave rise to mycelium formation. Some of these spores formed chains. Chlanydospores were not formed. Wernicke (*Central. f. Bact. u. Parasit.*, xii, 1892) has observed similar forms before but regarded them as protozoa.

(340) Agglutinative Property in Typhoid Blood Conferred on a Child in Utero.

Zängerle (*Münch. med. Woch.*, June 26th, 1900) relates the following case: A woman in the third week of typhoid gave birth to a full-grown female child. The latter was in every respect healthy; slept, fed, and passed natural motions. Two days after birth its blood gave a positive result examined by the Gruber-Widal serum test, and the mother's blood gave the same result. In this case the specific agglutinative property of the mother's blood was evidently transmitted *in utero*, though the child remained free of the disease itself. Three similar cases have been described and the author remarks that they throw considerable light on the immunity of children born of syphilitic parents, but showing no signs of the disease. Here also some agent capable of conferring immunity probably passes into the circulation of the fœtus through the placenta. The author does not argue that agglutinative power is synonymous with immunity, but suggests a relation and an analogy between them.

(341) Necrotic Broncho-pneumonia in Association with a Streptothrix.

Norris and Larkin (*Journ. Expér. Méd.*, vol. v, No. 2) reports two cases of this condition in which the clinical signs were those of extensive consolidation and bronchial catarrh throughout the lungs. Histologically in both cases the lesions consisted of intense exudative and necrotic inflammation of the bronchi and surrounding alveoli. In the bronchi and bronchioles were small masses composed of a network of streptothrix. The bronchial exudate of Case I introduced into the trachea of three rabbits produced pulmonary abscesses and empyema in one; that obtained from Case II was introduced into the ear vein of one rabbit and into the trachea of another, in both cases producing pulmonary abscesses and empyema. The streptothrix was recovered from these lesions. It could not be cultivated on the ordinary media, but grew upon fresh sterile kidney surface.

AN EPITOME
OF
CURRENT MEDICAL LITERATURE.

MEDICINE.

(342) Precocious Obesity.

It is sometimes supposed that a considerable degree of fatness in a child is a sign of health, but according to Chauffard (*Journ. de Méd.*, March 10th, 1900) it is a sign of degeneration, and unless treated may end fatally. The writer had under his care a man, aged 34, of middle height, and of very excessive obesity. From early childhood this had been the case, and it was discovered that there were several instances in his family of hereditary obesity. Examination showed considerable cardiac embarrassment and dyspnœa. He was put on milk diet alone, together with some doses of thyroid extract, and under this treatment he lost a good deal of weight in three weeks. He returned home and resumed his ordinary diet, on which he regained a kilogramme per diem. It was found that his heart was failing, and had ceased to react to digitalis and other tonics. The patient died of asystole. It is difficult to state exactly the pathogenesis of congenital obesity. In some, apparently, there is too rapid an assimilation of nutritive material, while in others combustion is not sufficiently rapid. It has also been supposed that there is some peculiar lipogenic ferment, but the evidence of this is not sufficient. In constitutional cases treatment is very much more difficult, especially in view of the fact that they are not infrequently gouty, diabetic, or the subjects of renal disease. A great deal also depends on the state of function of the heart and kidney, which are indeed the indications of most importance. Not infrequently there is tachycardia or arrhythmia. On *post-mortem* examination the muscular structure of the heart is generally found to be considerably affected. A point which has, so far, not been sufficiently studied is the thyroid gland. In the cases quoted by the author, this organ was double the normal size, and its structure profoundly altered, there being a condition which could best be described as a hypertrophic cirrhosis. In such cases the main line of treatment is, first, to impress on the patient the absolute importance of reducing his weight, otherwise the heart may be suddenly hampered, and give way. Next, to put him on a very limited diet, chiefly milk, and to order a carefully graduated scale of exercises. It is important that it should be judiciously increased, and it may be combined with massage. The administration of thyroid extract is undoubtedly of use according to the writer, but its action must be carefully watched. It is contraindicated in cases where there is severe cardiac embarrassment. When given it should be taken for a week at a time, followed by the administration of Carlsbad salts. If taken too frequently the result may be cardiac failure.

(343) Dermatitis Gangrænosa Infantum.

Judson Lipes (*Albany Medical Annals*, vol. xxi, No. 1, 1900, p. 1) first reviews the subject generally, and gives a bibliography. He then relates a case which came under his own observation in a female child, aged 2 years and 3 months. The points of interest about the case are (1) the fact that the condition commenced as a large flattened bulla, which ruptured spontaneously, the derma becoming gangrenous and gradually sloughing off from the periphery towards the centre. (2) The large size of the lesion, which extended from a little below the umbilicus upward for a distance of 12 to 14 cm., the transverse diameter being somewhat less. (3) A short time after this lesion appeared, erythematous spots, from a pea to a 25-cent piece in size, were observed about the anterior part of the neck and upper anterior margin of thorax. In some bullæ developed, but there was no gangrene: a bulla also appeared on the right upper eyelid and one on the scalp. (4) There was a trace of albumen in the urine, which was otherwise normal. (5) The fourth week after the appearance of the large abdominal lesion a condition corresponding to that of post-diphtherial paralysis was observed. The legs were symmetrically paralysed and the knee-jerk was lost. There was also weakness of cervical muscles. Recovery came about slowly, the loss of motion in the legs enduring longest. Recovery was ultimately perfect. Lipes considers the bullo-gangrenous lesion was due to a paralysis of the arterioles, this being a primary manifestation of a toxic neuritis caused by the presence or elimination of some chemical product of the growth of some organism—in all probability the tubercle bacilli—which showed itself later in the temporary paralysis of the legs. There was a decided tuberculous history in the case. It is on this basis alone that Lipes raises his hypothesis. The author recommends quinine and arsenic internally, *plus* local antisepsis—by boracic acid solutions, etc.

(344) Tertiary Syphilitic Diarrhœa.

Fournier and Lereboullet contribute an article on this subject to the *Gaz. Hebdom. de Méd. et de Chir.* of July 8th, 1900. The latter describes the case of a man the subject of chronic diarrhœa for 18 months, which had resisted all treatment. The first symptom was hæmorrhage from the bowel, recurring after several weeks, and gradually succeeded by diarrhœa with colic and rectal tenesmus. The patient was cured by antisyphilitic treatment; his attack of syphilis had occurred 15 years before. Galliard (*Presse Méd.*, January, 1897) has described the very diverse lesions which tertiary syphilis may produce in the intestine, miliary gummata, discoid infiltrations varying in thickness and extent and in later stages going on to ulceration, primary ulceration rarely proceeding to perforation, and cicatricial contraction and stenosis. The syphilitic ulceration gives rise to no specific symptoms, and the diarrhœa, etc., is often no doubt attributed to other causes. Fournier believes that it usually occurs in the course of the disease; there is nothing characteristic about the diarrhœa except its resistance to ordinary remedies, and its tendency to relapse, even after apparent cure with antisyphilitic remedies.

(345) Neuroses of Childhood.

De Merritt (*N. York Med. Journ.*, June 16th, 1900) believes that hysteria and neurasthenia are common causes which, starting in childhood, produce grave neurotic disturbances or mental troubles of later life. The symptoms begin insidiously in children, and are often passed over by the practitioner, who may assure the parents that the child will "outgrow" it. The child's disposition may be irritable and eccentric, with high-strung nerves. For want of appropriate and continuous training such children may grow up with exhausted nervous systems, to swell the great army of neurological wrecks so common at the present day. Heredity is both direct and indirect in these cases—direct in that the child is born with an unstable cerebro-spinal nervous system, and indirect in that neurotic parents nag and scold their children incessantly, and yet have not will power enough to enforce real discipline, with the result that the child's mental equilibrium is upset. Overstudy in schools is not *per se* a cause of neuroses except in predisposed children. German children study harder than American children, yet the former break down less frequently because their home life is more sedate and restful, and because precocity is suppressed, not encouraged, as in American families. Exercise in moderation and pursued in the open air is a great aid to treatment. The infectious fevers of childhood, anæmia, and poor food favour the development of neuroses. The neurotic child may show tendencies to hysteria or to neurasthenia; but it is hard to strictly separate these two—and, indeed, differentiation is of little practical importance. The more common symptoms exhibited are great irritability of temper, insomnia, *pavor nocturnus*, a tendency to lie and to invent plausible falsehoods merely for the love of so doing, masturbation, fits of crying and screaming with passion on little or no provocation, a facility for malingering or feigning, and an excessive desire for sympathy. Rest from school study should be enjoined in the few cases where this may be needful, because the mental and moral discipline of school life acts as a tonic to the brain, and may prevent the hypochondriac tendency. School gymnastics, now almost universally taught, are an adjuvant towards brain hygiene, and should be encouraged. Neurotic and hypochondriacal parents must be warned not to display their defects

before the child, who readily copies them. Among drugs—which are only of secondary importance in treatment—the bromides and hyoscyamus are useful, but must be given with caution, and warm sponge bathing before bedtime will soothe the nervous irritability and help to procure sleep and brain recuperation. Treatment and watchfulness for years will overcome many of the tendencies to nervous diseases, and perseverance is necessary.

(346) The False Cardiac Hypertrophy of Adolescence.

HUCHARD describes a case (*Journ. de Méd.*, July 10th, 1900) of what he calls false cardiac hypertrophy. The patient was a boy aged 16, whose family history was negative. He complained of palpitation and general fatigue. There was loss of weight, but no cough. He was supposed to have cardiac hypertrophy by some, and pericarditis by others. This case, according to Huchard, represented what has been described by Sée and others as hypertrophy of growth, and by Stokes as palpitation of puberty, a condition which the writer absolutely denies. Huchard points out that in very many young subjects, even in the absence of tubercle and rachitis, the chest may be ill-shaped, being long and narrow, with diminution in the transverse and antero-posterior diameters, and showing some bilateral flattening. In these cases it is not that the heart is over-developed, but that the thorax is undersized, and thus its movements are hampered. The apex may appear lower, and its impulse is somewhat more heaving than should be the case. These are all accounted for by insufficient thoracic space. This interference with cardiac action may be followed by changes in the heart itself, and even real hypertrophy may result. The heart is compelled to press considerably against the thoracic wall at each systole, and it is not surprising, therefore, to find that it undergoes some increase in size in many cases as time goes on, though this is not met with in all. The recognition of this point is, of course, important therapeutically. The correct treatment consists in gymnastic exercises and methods to enlarge and extend the chest—a line of treatment which is the opposite of that required in true hypertrophy of the heart.

(347) Pupillary Anomalies in Idiots.

KOENIG of Daldorp Asylum (*Journal of Mental Science*, July, 1900) has made several observations on pupillary anomalies in paralysed and non-paralysed idiot children, and attempted to trace their relation to hereditary syphilis. A search through literature only gives 3 incomplete cases, quoted by Freund in his well-known monograph (*Die infantile Cerebrallahmung*, 1897). The clinical link uniting cases of uncomplicated idiocy and such cases as are associated with paralysis is represented by a group of symptoms, such as epileptiform and hysterical seizures, athetoid, choreiform, and myoclonic disorders of movement, and finally, disturbances of the ocular apparatus—namely, nystagmus, ophthalmoplegias, neuritis, and optic atrophy. Fuchs, in a recent memoir, giving notes of 100 cases of infantile cerebral paralysis, reports in one case an inequality of the pupils, but no other anomalies. Koenig's material is divided into three groups. Group A shows a more or less frequent alternate dilatation of the right and left pupil (alternate mydriasis). Group B showed transitory sluggishness of the pupil to light, with slight inequality and a moderate degree of paralytic exophthalmos. Group C comprised the majority of the cases, and included a chronic state of irregular pupillary activity. Eleven cases—8 boys and 3 girls—belonged to this group, the ages varying between 7 and 15 years. In all instances but 3 the children were mentally deficient from birth, or were noticed to be defective in intelligence before the close of the first year. All these patients but one had histories of convulsive attacks at some time or other of life, followed by paralysis or mental enfeeblement. Several of these cases were of syphilitic parentage. Koenig concludes that, having regard to the heterogeneous mass of cases of congenital and early weakmindedness in which parental syphilis plays an etiological part, we may recognise three varieties—namely, non-paralysed idiots, paralytic idiots, and infantile and juvenile general paralytics. In every one of these three groups abnormalities of pupillary action may be present. This may be regarded as the rule in juvenile general paralysis, and in many cases of brain syphilis. It is the exception, however, in infantile cerebral palsy proper, and still more so in ordinary non-paralytic idiocy.

(348) Cutaneous Oxyuriasis.

BARBAGALLO (*Gazz. degli Osped.*, September 16th, 1900) records 4 cases where the presence of oxyurides gave rise to a special form of intertrigo in the anal, perineal, and inguino-crural region. The rash is usually of an intertriginous character. In the first period the oxyurides emigrate and by irritating the skin prepare the way for a permanent lodgment, whereon they nourish themselves and deposit their eggs. It is not a common condition, and has an uncertain duration; it is not confined to any particular age, and is amenable to the usual anthelmintic treatment.

SURGERY.

(349) Compression of Pedicle of Movable Kidney by Distended Gall Bladder.

REYMOND (*Rev. de Chir.*, June, 1900) reports an instance of the very rarely observed association of movable kidney with distension of the gall bladder due to biliary lithiasis. The patient, a woman aged 33, came under observation with intense intermitting pain in the abdomen on the right side, much general abdominal distension and tenderness, diminished flow of urine, and high fever, with marked prostration. The local and objective signs indicated both a distended gall bladder and a movable and distended kidney. There was a distinct pear-shaped swelling in the region of the former organ, and behind this could be felt, on combined abdominal and lumbar palpation, a more extended tumour presenting the characteristics of an abnormally mobile and enlarged kidney. The author performed nephropexy, and, on exposing the kidney, found that it was almost twice its normal volume, and much congested. In front of the organ, and attached to the renal pelvis, could be felt a firm mass, which corresponded to the anterior abdominal tumour, and gave the impression of its being a gall bladder distended by fluid and calculi. After an interval of a week, during which the kidney had rapidly regained its normal size, cholecystostomy was practised, and 60 grams of purulent fluid and four calculi, one of which measured 4 cm. in length and 3 cm. in thickness, were removed from a much distended and adherent gall bladder. The patient ultimately made a complete recovery, but persistence of a biliary fistula gave some trouble, and necessitated a plastic operation.

(350) The Best Method of Collecting the Urine from the Ureters for Diagnostic Purposes.

HARRIS (*Ann. of Surg.*, August, 1900) discusses the relative values of the urethral catheter and the urine segregator in the diagnosis of renal disease. In summing up he finds that catheterisation of the ureters has a field of application which is absolutely distinct, in the sense that no other means at disposal accomplishes the objects of determining the nature and location of obstructions of the ureter; of locating the ends of a severed ureter; of serving as a guide in certain intrapelvic operations; of tapping and draining fluid accumulations in the renal pelvis, and of fulfilling certain therapeutic purposes such as dislodgment of calculi and irrigation of the renal pelvis. Catheterisation of the ureters simply for the purpose of collecting urine for diagnostic purposes has its drawbacks and limitations, among which may be mentioned temporary anuria due to the presence of the catheter in the ureter; contamination of the urine with blood and epithelial cells from the the ureter; and the danger of infecting a healthy ureter and even the kidney. Catheterisation of a healthy ureter has been regarded as unjustifiable in cases in which the bladder is infected or the opposite kidney tuberculous. If this objection be generally recognised, the benefits of this aid to diagnosis will be denied to a large class of patients. The segregator likewise has its limitations, and cannot be applied with any prospect of success in cases in which diseased and painful conditions of the bladder interfere with the proper use of the instrument. But for the differential diagnosis of certain tumours of the abdomen; for determining which kidney is diseased and the

functional capacity" of each; for making out whether the bladder is infected or not; and for differentiating between certain bladder and renal infections the segregator gives results that are perfectly reliable. In infected cases it has the advantage over the urethral catheter of being free from the danger of carrying disease to a healthy kidney.

(351) Paracentesis and Drainage in Hydrocephalus.

Montini (*Gazz. degli Osped.*, August 12th, 1900) records the case of a hydrocephalic child aged 3 upon whom he operated with success. The head measured 63 cm. in the suboccipito-bregmatic circumference, 66 cm. occipito-frontal, and 55 cm. mento-frontal. The child was semi-idiotic, squinted, and showed all the mental and physical signs of hydrocephalus. The skull was trephined just behind the coronal suture with a trephine 2 cm. in diameter, a trochar was then slowly plunged into the ventricle and about 350 grams of fluid let out. As the condition of the child became alarming the operation was hastily finished and a horse-hair drain left in. The cerebral fluid continued to drain out for seven days, and altogether about 900 grams of fluid came away. The child is still alive a year after the operation. The squint is less marked, and there have been no convulsions for several months; the movements of the child show some attempt at co-ordination and are more objective in their character.

(352) Operative Treatment of Cortical Epilepsy.

Lunz (*Deut. med. Woch.*, June 7th, 1900) publishes two cases of cortical epilepsy which present much interest with regard to the nature of the initial lesion in both, and to the good results which followed craniectomy in one of the patients. There could be no doubt, the author asserts, of the cortical nature of the epilepsy in both cases, and the localisation of the morbid process could be strictly defined in each. In the first case the upper part, and in the second case the middle and lower parts of the central convolutions were affected. The subject of the first case was a woman, aged 53, who in early life had suffered from suppurative and, probably, tuberculous disease of the left shoulder. On removing a portion of the cranial vault over the region diagnosed as that of the initial lesion, the author found that the dura mater was thickened, and adherent on the one hand to the wall of the skull, and on the other to the pia, which latter membrane was also adherent to the surface of the brain. This condition was regarded as one of cicatricial thickening and adhesion due to some old morbid process, probably of a tuberculous nature. The results of the operation in this case have, it is stated, been very good. The patient has remained almost quite free from the severe epileptiform attacks by which she was [illegible] monthly troubled every day before [illegible] treatment, having [illegible] very slight one. The author acknowledges, however, that the interval, which does not exceed four months, is too short to afford any guarantee of complete cure with regard to the convulsive attacks. In the second case reported by the author, the intracranial morbid condition consisted in adhesions of the dura and pia mater over the lower third of the fissure of Rolando, and also in a deposit in and about the region of nodular growths, which presented under the microscope the characteristic features of tubercle. The operation was followed, in the course of about three weeks, by a return of severe and frequently repeated convulsive attacks.

(353) Spontaneous Fistula from Gastric Ulcer.

Kronheimer (*Deut. Zeitschr. f. Chir.*, October, 1899) reports a case verified by *post-mortem* examination after an unsuccessful operation. The patient was aged 45, subject to anæmia for nine years; she had never been pregnant, and the period had ceased for two months. Dyspeptic pains had lasted for some time, and fixed pain was at length localised to a point a little below the left hypochondrium. At length violent vomiting and paroxysmal aggravation of the fixed pain took place. The pain was trifling when the patient fasted. A hard swelling developed at the site of the pain five months before admission into hospital, it grew red, then soft, and burst a fortnight before; dark fluid and pieces of food began at once to escape, and the pain diminished. Emaciation was advanced, the integuments were intensely irritated. Fluids drank by the patient escaped in jets through the fistula, and very little nutritive material was digested, hence feeding through the mouth or through the fistula was impracticable. Nutrient enemata were given, but the patient clearly could not be kept alive for long by such means. Hermes undertook an operation for the excision of the fistula. But the patient took the anæsthetic badly, and the heart's action was very weak; there was also double bronchitis. He therefore, having made a median incision above the umbilicus, did an enterostomy, opening the jejunum directly after its transition from the third part of the duodenum. His aim was to feed the patient through the jejunal fistula till her strength would allow of a more complete operation. This was practicable, but peritonitis set in, and the patient died on the ninth day. A large oval chronic ulcer was found in the anterior wall of the stomach, corresponding to the fistula.

MIDWIFERY AND DISEASES OF WOMEN.

(354) Menstrual Condition of the Average Girl in Average Health.

George L. Engelmann, of Boston (*Med. Record*, December 1st) has collected facts on this point from the records of 4,873 cases from high and normal schools, colleges, and department stores. The girls were between 15 and 26 years old, the majority between 18 and 22, in rather better than average health—in good health, and in numbers sufficient to admit of positive deductions as to what may be termed normal or average menstruation. In brief, the menstrual period proper was intensified by the increase of all vital energies, followed by a depression which appeared with the coming of the flow. Under ideal conditions and in perfect health the physiological status was such that this epoch, preceded by a day or two of heightened activity, was marked by a moderate lassitude, mental and physical, the flow persisting for from four to five days, and recurring at regular intervals of about twenty-eight days. It was a period of heightened susceptibility that quickly recorded any variation from the normal; excitement or exertion, or fatigue, mental or physical, were promptly reflected by variation in the function, and in our everday life such disturbing elements constantly occurred, so that conditions actually existing varied greatly from this ideal. The average period of the average girl in average health presented very different features: Regularity in 50 per cent. of the cases only; recurrence every 28 days in 30 per cent., varying most frequently from 26 to 42 days, 45 per cent. being over 28. The duration varied from 2 to 7 days, average 4 to 6. From 66 to 70 per cent. suffered more or less, the number of sufferers varying, according to age and nature of occupation, between 30 and 90 per cent. Lessened ability for exertion, mental or physical, was admitted by 60 per cent. Some few were habitually incapacitated from work, and 30 per cent. occasionally. The function of the girl in good health, under modern conditions of life, was by no means an ideal one in Engelmann's judgment; and, in fact, the functional health of the American girl—the coming mother of American men—was far from what it should be by right of inheritance and surroundings. This fact practitioners must recognise, and upon them and educators devolved the duty of study and correction of the evil.

(355) The Circulatory Apparatus in Pregnancy.

E. Bonomi (*Annali di Ostetricia e Ginecologia*, xxii, 753, October, 1900) has investigated anew the question of cardiac hypertrophy in pregnancy. From clinical observations upon 28 pregnant women and from the examination of various animals (cow, sheep, rabbit, cat, guinea pig) in a pregnant and unimpregnated state, the conclusion is drawn that there occurs a physiological and transitory hypertrophy of the cardiac muscular fibres. Observations of the blood of both hospital and private patients showed that pregnancy induced a state of slight anæmia, so slight as not usually to produce morbid symptoms; this tended to disappear with the establishment of lactation. The cardiac hypertrophy is to be accounted for by the increase in the mass of blood and in the abdominal pressure,

along with the addition of a new zone of circulation and the irritant action of excrete fœtal products circulating in the maternal blood.

(356) The Ovary in Mollities Ossium.

Scharfe (*Centralbl. f. Gynäk.*, No. 45, 1900) has carefully examined three pairs of ovaries removed from patients with mollities. Two were extirpated by vaginal hysterectomy on subjects not pregnant, the third were removed at a Porro's operation at term. The evidence was entirely negative, nor was there any distinction between the pair removed from a pregnant subject and the others. So far the effect of castration does not seem to depend on the removal of any pathological conditions resident in the ovary.

THERAPEUTICS.

(357) Treatment of Lupus.

Beilage (*Dermat. Centralbl.*, June, 1900) recommends the following formula, proposed by Unna: Acidi salycilici, liquor antimonii chlor. ad. 2; creosoti, ext. cannabis ind. ad 4; adip. lanæ S. The antimony is said to kill the bacilli, the creosote and cannabis indica allay the pain, and the salicylicacid aids penetration. When the disease is deep, liquor antimonii chlor. is applied on wooden matches, the ends of which are cut off and left *in situ* for 48 hours.

(358) Calomel Injections in Syphilis.

Fournier *Rev. de Therap.*, November 1st, 1900) gives his experience of the value of calomel injections in the treatment of syphilis. The method must not be regarded as a routine treatment, but as an exceptional one to be used in certain severe conditions, such as spinal and cerebral syphilis, iritis, phagædena, chronic palmar and plantar syphilides, ulcerating tuberculous syphilides, glossitis, and tertiary laryngeal and pulmonary syphilis. It should be regarded as a temporary measure to be used for one or two months till the severe condition is improved, when it should be replaced by more ordinary treatment. In the author's opinion, it is the most powerful agent we possess against syphilis. The technique is as follows: The calomel should be sublimed and not precipitated, as the latter is apt to form lumps. It is afterwards washed with boiling alcohol and then dried. The best vehicle is sterilised olive oil. A Pravaz syringe is used holding a gram, which contains 5 centigrams of calomel. The needle is introduced deeply into the gluteal muscles, and a slight interval allowed to elapse before the injection is made, to see if any blood appears. If this occurs the injection should not be made, since there is danger of pulmonary embolism. Fournier quotes a case in which this occurred. The average dose is 5 centigrams injected every seven or ten days. This may be increased to 7, 8, or 10 if necessary. In women, 3 or 4 centigrams are enough. Four or six injections are usually sufficient. The author remarks on the rapid action and beneficial results in many cases, and quotes several severe cases in his clinic which were cured by a few injections, sometimes only one. On the other hand he points out that such good results do not always follow, and sometimes the method fails. The objections raised against the method are the occurrence of stomatitis, gastro-enteritis, toxic effects, local reaction, and pain. Fournier, with doses of 5 centigrams, has seldom observed any bad mercurial symptoms; swelling and induration of the buttocks are frequent, but abscess is rare. Pain is the chief complication, and occurs in 3 out of 5 injections. It is sometimes very severe, but in the author's opinion the method should not be abandoned on that account in the severe and intractable cases in which he recommends it.

(359) The Germicidal Power of Ethylic Alcohol.

Bertarelli (*Il Policlinico*, October 1st, 1900) has tested the germicidal properties of ethylic alcohol in various strengths, from 25 per cent. to 100 per cent. Silk threads were impregnated with various bacilli (for example, B prodigiosus, pyocyaneus, staphylococci, vibrio, B. typhoid., etc.), and then immersed in alcoholic solutions of varying strength. From these researches alcohol appears to have only a moderate antiseptic value, and the more concentrated the solution the less the antiseptic power; 50 per cent. solutions are the most efficacious. Perhaps the reason of the comparative inefficacy of the stronger solutions is due to the fact that they cause greater coarctation of the peripheral masses of bacilli, and so leave the central masses more or less untouched. In spite of its low bactericidal power alcohol hinders the development and later vital manifestations of the micro-organisms. Alcohol appears to have an inhibitory effect on the antiseptic power of certain germicides (for example, corrosive sublimate) dissolved in it, and the greater the alcoholic strength the greater this inhibitory power.

PATHOLOGY.

(360) Diffuse Traumatic Amyotrophic Change.

Ballet and Bernard describe several cases (*Arch. Gén. de Méd.*, May, 1900) which have come under their own observation showing extensive atrophy of the limb muscles as the result of injury involving the peripheral parts of the extremity. The lesions in their cases consisted in penetrating wounds of the hand or forearm, bullet wounds, etc., together with one case in which the lesion was an arthritis of the wrist coming on in a labourer. In all of these cases the muscles of the shoulder group, upper arm, etc., showed atrophy. In each of these cases the most feature consisted in the appearance of ex limb, all the mu in size, which was progressive, though slow, and was accompanied by corresponding weakness. Sensation, objective and subjective, showed no departure from normal, except at times a slight amount of itching and tingling, which appeared considerably later than all the other results. In each case electrical examination showed decrease of faradic and galvanic stimulation, but no reaction of degeneration. The authors discuss the probable nature of this wasting. The idea that naturally occurs is that of an ascending neuritis, but on comparing the cases quoted with authentic instances of this affection certain differences are at once observed. The neuritis comes on very shortly if not immediately following the wound, and the nerve which has been injured is the only one to show the neuritic change as a rule. In the cases under consideration, however, there were no neuritic symptoms dating from the lesion, the nerve trunks remaining to all appearances healthy between the wound and the upper portion of the member. The authors state that in such cases certain chromolytic changes take place in the cornual cells corresponding to the limb affected, changes to which the name reaction from a distance has been applied, and which was originally described by Nissl. Such changes may be found under a variety of circumstances, such as wounds in the hand or foot, injuries to branches of the cauda equina, etc. It would appear according to the writers that when the terminations of the nerve are injured that this reacts on the cells of the neuron, which as a consequence suffers thereby, inducing the usual changes characteristic of degeneration of these cells.

(361) Congenital Absence of Fibula.

W. A. Wood (*Intercol. Med. Journ. of Australasia*, v, 260, May 20th, 1900) reports two cases of congenital absence of the fibula. In one of these, an infant 6 months old, no fibula was to be felt in the right leg, although both malleoli were present. The foot had three small toes and one large one, which the *x* rays showed to be a fusion of two toes. The right tibia had a slight antero-posterior bend. The left leg had no fibula; there was an acutely curved tibia with anterior convexity; the left foot was in talipes valgus position, and had two small toes and one big one. There had been constant pain in the uterus during pregnancy. In the other case, a child 2½ years old, the birth had been a face presentation. The thighs were much bent, and had been so at birth. The mother was normal, but had had a miscarriage of twins and a deadborn infant. Both the thighs were arrested in de[illegible]ent, the skin of the perineum [illegible]ut 1 inch from the knee. [illegible] was absent on the left side. [illegible] was dislocated wholly ou[illegible]t. He were three small toes [illegible] one. The [illegible] The *x* rays [illegible] dislocation of both [illegible]; in determining [illegible] kidney is diseased and the
